Abstract

A laboratory scale study was set up to investigate the ammonia (NH_3), nitrous oxide (N_2O), carbon dioxide (CO_2) and methane (CH_4) emissions during storage of untreated pig and cattle slurry and the fractions (solid and liquid) obtained by mechanical separation. The solid and liquid fractions were obtained from the same untreated slurry by means of a lab scale mechanical separator.

The manures were stored for a period of 30 days in open vessels (1500 cm^3 capacity) in two temperature controlled rooms which were kept at 5±0.5 °C and 25±0.2 °C. Gaseous emissions were determined using a dynamic chamber method and Infrared Photoacoustic Detection (IPD).

Over the storage period, gaseous emissions from pig manures were significantly (P<0.05) higher than those from cattle manures. N_2O fluxes of up to 232 mg m^{-2} h^{-1} were measured but from pig solid fraction only. Between 40.8% (from pig liquid fraction stored at 25 °C) and 3.60% (from untreated cattle slurry stored at 25 °C) of the initial nitrogen content of the manures was lost as

NH$_3$. Over the 30-days storage period, the predominant emission of carbon was in the CO$_2$ form. Total C-CH$_4$ losses expressed as a percent of the carbon initially present in the volatile solids (C-VS) ranged from 0.60% to 12.8% for pig manures and from 0.23% to 1.56% for cattle manures. The mechanical separation of cattle slurry increased by up to 30% the emissions of CO$_2$ equivalents to the atmosphere during the storage of the separated fractions if compared with the slurries. Results indicated that NH$_3$, N$_2$O, CO$_2$ and CH$_4$ emissions were affected by the interaction between a number of variables, including storage temperature, chemical characteristics and type of manure. Results also indicated that mechanical separation does not reduce emissions but has the potential to increase the emissions of CO$_2$ equivalents to the atmosphere during the storage of the separated fractions.

1. Introduction

Animal excreta can contribute to eutrophication of groundwater and surface waters as a result of nitrogen (N) and phosphorous (P) enrichment (EEA, 2005) and are considered an important source of ammonia (NH$_3$), nitrous oxide (N$_2$O), carbon dioxide (CO$_2$) and methane (CH$_4$) production (Van Der Hoek, 1998; Amon et al., 2001). While N$_2$O, CO$_2$, and CH$_4$ are greenhouse gases affecting the global environment and climate change, NH$_3$ contributes to eutrophication and acidification of soils and also indirectly contributes to N$_2$O emissions by increasing the N-cycling in natural ecosystems (Olesen, 2005). Modern intensive animal production methods have increased the volume of manure in the slurry form (Menzi et al., 2002). Several techniques have been developed to manage livestock slurries as cheaply and conveniently as possible and to reduce potential risks of environmental pollution. Among these techniques, solid-liquid separation is a technology that separates slurry into a larger liquid fraction and a minor solid fraction which has a greater concentration of nutrients than

75 the liquid (Kroodsma, 1986; Møller et al., 2000). This could enable more cost-effective transfer of

76 nutrients from areas of high livestock density where they may be in surplus to areas with a lower

77 livestock density. Nevertheless, little data concerning NH_3, N_2O, CH_4 and CO_2 emissions during

78 storage of both liquid and solid fractions are currently available.

79 In consequence a laboratory-scale trial was carried out to better characterize the main parameters

80 affecting NH_3 and GHG emissions from the storage of untreated liquid manure and both the solid

81 and liquid fractions derived from mechanical separation of slurry. The following aspects have been

82 analyzed:

83   1) the NH_3, CO_2, CH_4 and N_2O emissions from the storage of:

84   A. cattle and pig untreated liquid manure

85   B. solid fractions obtained from both untreated liquid manure after solid-liquid

86   separation

87   C. liquid fractions obtained from both untreated liquid manure after solid-liquid

88   separation

89   2) the effects of temperature and chemical characteristics of the three products listed in point 1)

90   on such emissions.

91

92   **2. Materials and methods**

93 The trials were carried out at Leibniz-Institute for Agricultural Engineering Potsdam-Bornim

94 (ATB), Germany, in environmentally controlled conditions by means of two climatic rooms.

95 Fresh slurry was collected from commercial farms. The next day (cattle; pig two days after) it was

96 separated and stored in vessels in the emission lab of the institute and measurements began.

97 The solid and liquid fractions (B and C) were obtained from the same pig and cattle untreated slurry

98 (A) by means of a laboratory-scale mechanical separator. This latter was made up of (Fig. 1): a

99 1500 cm^3 bowl with handle; a stainless steel disc (screen) with circular holes 2.3 mm in diameter; a

100 stainless steel blade integral with a crank; a container collecting the liquid fraction.

101 A press zone was created fitting the blade to the disc by means of a horizontal bar and a spring.

102 After filling the bowl with the untreated slurry, the blade is manually rotated using the crank and

103 the slurry separated in the press zone. The liquid fraction runs through the disc's holes into the

104 container while the solid fraction remains in the bowl and is collected afterwards. The total input of

105 each untreated slurry (100 kg), as well as the amounts of solid (18.1 kg for cattle and 7.80 kg for

106 pig) and liquid (81.9 kg for cattle and 92.2 kg for pig) recovered, were weighed and recorded. The

107 bulk density of the solid fractions (cattle and pig) was estimated to be 0.40 t m^{-3}.

108 Immediately after mechanical separation, samples of 1000 cm^3 of each of the investigated materials

109 were stored for a period of 30 days in open vessels (1500 cm^3 capacity, 0.20 m height, 0.10 m base

110 diameter and 0.095 m top diameter) in two temperature-controlled rooms which were kept at 5±0.5

111 and 25±0.2 °C. During the test period observations of crust formation and reduction of volume were

112 carried out. Four replicates of each product were tested so that for each type of untreated liquid

113 manure (pig or cattle) a total of 12 vessels were used per climate room.

114 The samples were analysed for pH, total solids (TS), volatile solids (VS), total Kjeldhal nitrogen

115 (TKN), total ammoniacal nitrogen (TAN), and organic acids at the beginning and at the end of the

116 investigation period. Initial and final slurry analyses are given in Table 1.

117

118 Flux measurements were carried out using infrared photoacoustic detection (IPD) and the dynamic

119 chamber method described by Berg et al. (2006). This method allows the comparison of the effect

120 of different treatments on gaseous emissions during manure storage, under standardized

121 experimental conditions. Different conditions, such as volume to surface ratio of the manure stores,

122 in the lab and on farms may yield different gas fluxes. Therefore, this fluxes cannot be used for

123 calculating fluxes from on farm storage facilities without further validation. Accordingly, the

124 slurries were stored in open vessels using the dynamic chamber method set up only during

125 measurements. Before starting the measurements each vessel was closed with an air-tight lid

126 provided with two ports for air inlet and outlet (Fig. 2). Air inlet port was connected in an airtight

127 way with a flow meter and a compressor. The headspace (chamber) between the slurry surface and

128 the lid was then ventilated with compressed air to create an airflow through the dynamic chamber.

129 The air exchange inside the chambers was adjusted by the flow meters so that the air in the

130 headspace was always changed once per minute. Measurements were carried out four times a week

131 according to the following scheme:

132 1) lid closure at time t = 0 min;

133 2) between t=0 and t= 20 min the chamber was only ventilated to achieve steady conditions inside

134 the chamber;

135 3) t= 20 min beginning of the exhaust air sampling;

136 4) t= 36 min end of the exhaust air sampling and vessel opening.

137 The gas concentrations in the inlet (atmospheric) and outlet (exhaust) air were analyzed by the

138 INNOVA system 1312 Photoacoustic Multi-gas Monitor and Multipoint Sampler. The system

139 provided a real time analysis of 4 gases (NH_3, N_2O, CH_4 and CO_2) plus water vapour. Measured

140 data were related to standard conditions (25 °C and 100 kPa) and stored in a database. Exhaust air

141 leaving each chamber was sampled for 16 min. The instrument needed 2 min to analyze one sample,

142 thus, 8 values were recorded on each measurement occasion. The first 3 values were discarded and

143 the mean of the remaining 5 recorded values was considered representative for the measurement.

144 Gas fluxes F_j in mg m^{-2} h^{-1} were determined according to:

145
$$F_j = Q \frac{\left(C_{ex.j} - C_{in.j}\right)}{A} \tag{1}$$

146 where $C_{in.j}$ is the NH_3, N_2O, CH_4 or CO_2 concentration of air inlet the chamber in mg m^{-3}; $C_{ex.j}$ is

147 the NH_3, N_2O, CH_4 or CO_2 concentration of air outlet the chamber in mg m^{-3}; Q is the air flow rate

148 through the chamber in m^3 h^{-1}; A is the area of emitting surface covered by the chamber in m^2.

149 Time evolution of the gas fluxes were approximated by spline approximation functions, and by

150 integration of such approximations using adaptive Simpson quadrature formulas (Bronshtein et al.,

151 2003) cumulative losses φ_j in mg vessel^{-1} of each gas over the storage period (30 days) were

152 estimated.

153 Since measurements were carried out with 1000 cm^3 of all substrates respectively, in order to assess

154 the effect of mechanical separation on gaseous emissions, cumulative losses were corrected as

155 follows:

156 $$\Phi_j = \varphi_j \ \rho \qquad (2)$$

157 where Φ_j is the corrected cumulative loss of a specified gas in mg vessel^{-1}; ρ is a correction factor

158 that takes into account the mass Sc (kg) of separated liquid and solid fractions obtained after

159 separation of the untreated slurry Mc (kg), and the amount Me (kg) of untreated slurry, liquid and

160 solid fractions used for emission trials:

161 $$\rho = \frac{Sc}{Mc} \frac{1}{Me} \qquad (3).$$

162 The ρ values used are summarized in Table 1.

163 During storage trials, volume and surface area in contact with the air were the same for all tested

164 materials. Nevertheless, in practical conditions slurries are stored within tanks and solid fraction in

165 heaps on platforms. The slurry NH$_3$ emitting area is the horizontal cross section of the storage tank,

166 while for solid material it may be considered the surface area of a hypothetical frustum of cone

167 representing the shape of the heap. Considering an angle of repose of $1^1/_2$: 1 (horizontal : vertical)

168 (CNMP, 2002), the surface/volume ratio for the pig solid fraction was calculated to be 1.83 times as

169 much as pig slurry and 2.44 times as much as cattle untreated slurry for the cattle solid fraction.

170 Thus, to be able to assess the effect of mechanical separation on NH$_3$ emissions, measured NH$_3$

171 emissions from pig solid fraction and cattle solid fraction were therefore multiplied by 1.83 and by

172 2.44 respectively, assuming that the emissions per unit area were homogeneous. The emitting

173 surface area of the liquid fraction was assumed to be that of the untreated slurry.

174 To consider the effect of slurry mechanical separation on GHG emissions as a whole, the lC_jl were

175 converted into CO_2 equivalents by the Global Warming Potential (GWP) of the gases (NH_3: 3.1,

176 N_2O: 310, CH_4: 21) (IPCC, 1997).

177

178 Significant differences in results and all possible interactions were investigated using the ANOVA

179 procedure. Before analysis some of the parameters were log-transformed in order to fit a normal

180 distribution. For all the statistics, a significant level of $P = 0.05$ was applied. Assumption of equal

181 variance of different groups was tested using Bartlett's test. All statistical analyses were performed

182 with SPSS 12.0 for Windows.

183

184 **3. Results**

185 3.1 Slurry properties

186 After mechanical separation the liquid fractions produced by mechanical separation showed

187 significant reductions of TS and VS (Table 1). In contrast, the pH, TAN and TKN concentrations of

188 the liquid fractions were very similar to those of the untreated slurries. As expected, the TS and VS

189 content of the solid fractions were significantly greater than those for the untreated slurries. The

190 TKN content of the pig solid fraction was almost double the TKN content of the pig untreated

191 slurry, while the TKN content of the cattle solid fraction was approximately 1.4 times lower than

192 the TKN content of the cattle untreated slurry.

193 Analysis of the manures at the end of each experiment are given in Table 2 together with volume

194 reductions over the storage period.

195 Water evaporation occurred in all the samples throughout the storage period. As expected,

196 evaporation was higher from materials stored at 25 °C than 5 °C and was responsible for volume

197 reductions up to 45% of the stored slurries and of the relative increase of TS and VS amounts.

198 Appreciable volume reduction (30.6%) occurred for cattle solid fraction stored at 25 °C, low

199   reductions were observed for solid materials stored at 5 °C while no volume reduction occurred for

200   pig solid fraction stored at 25 °C.

201

202   3.2 Gaseous emissions

203   3.2.1 N_2O emissions

204   Over the storage period (30 days), no N_2O fluxes were measured from any material stored at 5 °C.

205   N_2O emissions from cattle and pig slurries stored at 25 °C occurred on a very few occasions only,

206   e.g. when the crust dried up, but the overall amounts were negligible. Very low concentrations,

207   sometimes slightly above the background concentration of N_2O, were also measured from the cattle

208   solid fraction. Appreciable N_2O fluxes were measured only from the pig solid fraction stored at

209   25 °C (Fig. 3). N_2O emissions started 8 days after the beginning of the storage period and reached a

210   peak of 232 mg m^{-2} h^{-1} at day 21. After that peak, the N_2O flux rapidly decreased to reach values

211   close to zero at day 25. The total nitrogen loss via the N_2O pathway accounted for the 4.71% of the

212   initial total Kjeldahl nitrogen (TKN) content of the solid manure (Table 3).

213

214   3.2.2 NH_3 emissions

215   Total losses of NH_3-N, expressed as a percentage of the initial TKN, (Table 3) ranged from 3.60%

216   (from untreated cattle slurry stored at 25 °C) to 40.8% (from pig liquid fraction stored at 25 °C).

217   Under the same storage conditions, there were no significant ($P>0.05$) differences between NH_3

218   fluxes from untreated pig slurry and from its liquid fraction (Fig. 4). In contrast, NH_3 fluxes from

219   untreated cattle slurry were significantly less than from its liquid fraction. NH_3 emissions were

220   higher at 25 °C than at 5 °C storage conditions, except when considering the pig solid fraction.

221   From this, significantly ($P<0.05$) higher NH_3 fluxes at 25 °C than at 5 °C were measured only at the

222   beginning of the storage period, while, after day 8 NH_3 fluxes were significantly lower at 25 °C

223   than at 5 °C storage conditions.

224

225 3.2.3 CO_2 and CH_4 emissions

226 During pig and cattle manure storage, the predominant emission of carbon was as CO_2 (Fig. 5 and

227 Table 3). Total losses of $C-CO_2$ expressed as a percentage of the carbon initially present in the

228 volatile solids (C-VS) of the manures ranged from 7.76% (from cattle untreated slurry stored at

229 5 °C) to 33.4% (from pig liquid fraction stored at 25 °C). CO_2 losses were always higher at 25 °C

230 and lower at 5 °C storage conditions.

231 Under the same storage conditions, CH_4 fluxes from the untreated slurries and from their liquid

232 fractions were not different ($P>0.05$) (Fig. 6), but total $C-CH_4$ losses over the storage period,

233 expressed as a fraction of initial C-VS content, were significantly ($P<0.05$) higher from liquid

234 fractions than from untreated slurries (Table 3). Under all storage conditions, total $C-CH_4$ losses

235 were higher from pig than from cattle slurries. $C-CH_4$ losses ranged from 0.60% to 12.8% for pig

236 manures and from 0.23% to 2.19% of the initial C-VS content for cattle manures. $C-CH_4$ losses

237 from pig manures were always consistently higher at 25 °C than those at 5 °C. However, the

238 emissions of CH_4 were only observed to be significantly ($P<0.05$) higher from cattle slurries stored

239 at 25 °C than at 5 °C during the first 3 days of storage. Thereafter, the emissions were lower from

240 cattle slurries stored at 25 °C than at 5 °C. $C-CH_4$ losses from cattle and pig solid fractions were

241 always significantly lower at 25 °C than at 5 °C storage.

242

243 3.2.4 Effect of slurry solid-liquid separation on gaseous emissions

244 Figure 7 shows the NH_3, CO_2 and CH_4 losses based on the corrected cumulative losses lC_jl and

245 expressed as a percentage of the lC_jl calculated for the untreated slurries (pig and cattle). It can be

246 seen that for pig slurry the combined emissions measured from the storage of the liquid and solid

247 fractions resulted in reduced NH_3 losses compared to the storage of the untreated pig slurry.

248 However for cattle slurry, the combined NH_3 losses measured from the storage of the liquid and

249 solid fractions were 7% and 45% higher than those measured from the untreated cattle slurry stored

250 at 25 C and 5 °C respectively.

251   The emissions from the storage of the two fractions increased the CO_2 emissions from 8% (when

252   compared to untreated pig slurry stored at 5 °C) to 104% (when compared to untreated cattle slurry

253   stored at 25 °C). During the storage of both liquid and solid fractions, CH_4 losses were 3% higher

254   for pig untreated slurry stored at 25 °C and 4% higher for cattle untreated slurry stored at 5 °C.

255   Instead, solid-liquid separation reduced CH_4 emissions by 8% for pig untreated slurry stored at 5 °C

256   and by 9% for cattle untreated slurry stored at 25 °C.

257   Combining the emissions of CO_2 equivalents from both liquid and solid fractions (Fig. 8), they

258   resulted in increased greenhouse gases emissions compared to the storage of the untreated slurries,

259   except when considering the pig untreated slurry stored at 5 °C. In this latter case the mechanical

260   separation had no effect in combined emissions of CO_2 equivalents.

261

262   4. Discussion

263   The small N_2O fluxes from cattle and pig slurries storage can be explained by the absence of crust

264   during most of the storage period. N_2O may be emitted during storage of manure either as a by-

265   product of incomplete ammonium oxidation or as a by-product of incomplete denitrification

266   (Oenema et al., 2001). The condition in liquid manure is strictly anaerobic, and neither process

267   occurs. In contrast, authors (e.g. Sommer et al., 2000; Berg et al., 2006) found N_2O production from

268   stored slurries, but only when a dry crust formed on the surface. These emissions occurred since

269   surface crust may contain a mosaic of anaerobic and aerobic micro–sites which are favourable for

270   N_2O production. Dry conditions, together with air filled porosity, may explain the occurrence of

271   N_2O production from pig solid fraction samples. On the other hand, separation of cattle slurry

272   produced a fibrous solid fraction with a compacted structure, this might have created an

273   environment with an oxygen concentration unsuitable for N_2O production.

274   Results confirm a positive relationship between ammonia emission and temperature found by other

275   studies (e.g. Ni, 1999; Dewes, 1996), but not in the case of the pig solid fraction. Total losses from

276   the pig solid fraction were 7.12 and 5.57% of the initial TKN content at 5 and at 25 °C storage

277   conditions respectively. This may be explained by ammonium oxidation by nitrifying micro-

278   organisms with N_2O production. NH_3 emission from manure decreased, therefore, as a greater

279   proportion of the NH_4-N was oxidized by nitrifying micro-organisms.

280   CH_4 losses from pig slurries significantly increased with temperature (Table 3). This is confirmed

281   by results of other studies (e.g. Husted, 1994), in which an increase of the CH_4 production with air

282   storage temperature was also found. The lowest CH_4 emissions from cattle slurries stored at 25 °C

283   with respect to those obtained at 5 °C were probably caused by the high water losses from the

284   slurries over time. As a consequence, a relative increase in concentration of constituents, such as

285   NH_3 and organic acids, which could be inhibitory to the methanogens (Kalle and Menon, 1984;

286   Angelidaki et al., 1999), occurred. This was proved by the CH_4 fluxes from both untreated cattle

287   slurry and liquid fraction stored at 25 °C which were observed to be high at the beginning of the

288   storage and to gradually decrease over time (Fig. 6). Additionally, Table 2 shows for cattle slurries

289   a relative increase in concentration of organic acids, which can be inhibitory to the methanogens, at

290   the end of the storage compared to the beginning of the storage (Table 1). The combined effect of

291   temperature and slurry concentration had no effect on CH_4 losses from pig slurries, probably due to

292   a more active methanogens population. According to Massé et al. (2003), manure from different

293   animals probably contains different species of anaerobic bacteria, which may be better adapted or

294   acclimatized to inhibitive components such as organic acids.

295   CH_4 emission reductions from the cattle and pig solid fractions stored at 25 °C could also be

296   explained by the high water losses over time. From the beginning of the storage period, when solid

297   fractions started to dry, air entered the pores previously filled with water. The high water losses

298   combined with low volume (1000 cm^3) of the samples in storage, resulted in a substantial reduction

299   of the anaerobic zone inside the cattle and pig solid fractions stored at 25 °C. Methanogenesis is

300   inhibited by low moisture content and oxygen availability in the manure. Furthermore, most studies

301   show CH_4 emission reductions due to the methane oxidation during the passage through the porous

302   surface layers of manure heaps (Olesen, 2005). Biological CH_4 oxidation is a process whereby

303 methane is oxidised to carbon dioxide and water by methane oxidizing bacteria (methanotrophs)

304 under aerobic conditions (Cicerone and Oremland, 1988; Kotsyurbenco, 2005). The substantial

305 reduction of the anaerobic zone over time and the biological CH_4 oxidation in the outer layers could

306 be the causes for lower CH_4 emissions from pig and cattle solid fractions stored at 25 °C.

307

5. Conclusion

309 Results from this study show that emissions of NH_3 and GHGs during the storage of animal

310 manures are influenced by different factors. Since emissions of NO_2, NH_3, CO_2 and CH_4 are

311 affected by microbiological, chemical, and physical processes, complex interactions exist. This

312 requires a whole system approach when pollutant abatement technologies have to be adopted.

313 Evidence from the present study suggests that mechanical separation of cattle and pig slurries does

314 not reduce emissions but has the potential to increase the emissions of CO_2 equivalents to the

315 atmosphere during the storage of the separated fractions by up to 30% if compared with the

316 untreated slurries. The emission potential of pig slurry was up to 3 times higher than that of cattle

317 slurry. It was determined under the laboratory conditions and assumptions as described. Thus, to

318 confirm these results, experiments should be made under on-farm storage conditions.
