## Abstract

In this paper, we propose two time of arrival estimators for ultra wideband signals based on the phase difference between the discrete Fourier transforms (DFT) of the transmitted and received signals. The first estimator is based on the slope of the unwrapped phase and the second one on the absolute unwrapped phase. We derive the statistics of the unwrapped phase. We show that slope-based estimation almost achieves asymptotically the baseband Cramer-Rao lower bound (CRLB), while the absolute-phase-based estimator achieves asymptotically the passband CRLB. We compare the proposed estimators to the time-domain maximum likelihood estimator (MLE). We show that the MLE achieves the CRLB faster than the DFT-based estimator, while the DFT-based estimator outperforms the MLE for low signal to noise ratios. We describe also how to use the proposed estimators in multipath UWB channels.

## 1. Introduction

UWB has received increasing attention for many applications like positioning since the FCC (Federal Communications Commission) allowed in 2002 the unlicensed use of the spectrum between 3.1 and 10.6 GHz [1].

Thanks to their ultra wideband (UWB) larger than 500 MHz, UWB signals can be used for highly accurate positioning using the time of arrival (TOA) technique. Many TOA estimators have been proposed in the literature, especially for impulse radio UWB (IR-UWB) signals. Most proposed estimators like the maximum likelihood estimator (MLE), the energy-based estimators, the auto-correlation-based estimators, the threshold-based estimators, and others are based on the time domain [2-10]. The drawback of time-domain estimators is that their precision is limited by the sampling frequency being used, and complex interpolation is required in order to improve the performance. Some other estimators for either electromagnetic or acoustic signals are using the discrete Fourier transform (DFT) of the received signal [11-17].

In this paper, we propose two estimators for the TOA based on the phase of the DFT of the received signal. The first estimator is based on the slope of the phase

and the second one, on the absolute phase. For both estimators, we first compute local estimates at the different frequency components, and then we combine them in order to find the global estimates.

The main three contributions of this work are that:

- we show that using the DFT, we can achieve asymptotically the CRLBs (Cramer-Rao lower bound) using very simple estimators requiring only few samples and a sampling rate equal to the signal bandwidth. In our approach, the sampling period is much larger than the achieved accuracy, while in time-domain-based estimation, the sampling period must be smaller than the required accuracy. Another advantage of DFT-based estimation is that we do not need to identify the main lobe of the autocorrelation of the used pulses like in time-domain estimation.
- we show that the MLE achieves the CRLB faster than the DFT-based estimator, while the DFT-based estimator outperforms the MLE for low SNRs.
- we compute the statistics of the unwrapped phase of a noisy signal.

The main difference between this work and the previous works using the DFT approach is that in the previous works, the TOA is not estimated based on the phase of the DFT [13,14], or the problem of phase

ambiguity is not investigated (by assuming the maximum time delay smaller than the period of the highest frequency component) [15,16], or the problem of phase ambiguity is solved using other approaches (Chinese remainder theorem [11,12] or recursive correction of the TOA estimate [17]). The proposed estimators can be used for IR-UWB signals as well as for multi-carrier UWB (MC-UWB) signals. Note that the main goal of this paper is to give the main ideas about DFT-based TOA estimation. Many improvements can be introduced in order to make the proposed estimators achieve performance closer to the CRLBs.

The paper is organized as follows. In Section II, we describe the system model. In Section III, we consider the MLE of the local phase and compute the statistics of the unwrapped phase. In Section IV, we derive the local slope-based and absolute-phase-based TOA estimators. In Section V, we derive the global slope-based and absolute-phase-based TOA estimators. In Section VI, we show how multipath UWB channel can be handled.

## II. System model

We consider a transmitter and a receiver communicating through an additive white Gaussian noise (AWGN) channel.

Denote by  $s(t)$ ,  $r(t)$  and  $n(t)$  the complex envelopes (baseband) of the transmitted signal, the received signal and the AWGN, filtered around central frequency  $f_c$  with a bandwidth  $B$  ( $[f_c - B/2, f_c + B/2]$ ).  $r(t)$  can be written as:

$$r(t) = \alpha e^{-j2\pi f_c \tau} s(t - \tau) + n(t) = \alpha e^{-j2\pi f_c \tau} s_\tau(t) + n(t)$$

where  $\alpha$  and  $\tau$  are the gain and the time delay of the channel, and  $s_\tau(t) = s(t - \tau)$ . After sampling at the rate  $B$ , we get:

$$r[m] = \alpha e^{-j2\pi f_c \tau} s_\tau[m] + n[m]$$

where  $z[m]$  denotes the sample of the signal  $z(t)$  at  $t = mT_s$  ( $T_s = 1/B$  is the sampling period).  $(n[m])$  is a white Gaussian sequence (i.e., the samples  $n[m]$  are independent and identically distributed (iid)). The variance of  $n[m]$  is given by  $\sigma_n^2 = 2N_0B$  where  $2N_0$  is the one-sided power spectral density of the AWGN.

Let  $R[k]$ , ( $k = -M/2, \dots, M/2 - 1$ ) be the DFT of  $r[m]$ :

$$R[k] = \sum_{m=0}^{M-1} r[m] e^{-j2\pi \frac{mk}{M}} = \alpha e^{-j2\pi f_c \tau} S_\tau[k] + N[k] \quad (1)$$

where  $S_\tau[k]$  and  $N[k]$  are the DFTs of  $s_\tau[m]$  and  $n[m]$ , respectively. As  $n[m]$  is a white Gaussian sequence,  $N[k]$  is

also white Gaussian with a variance equal to  $\sigma_N^2 = M\sigma_n^2 = 2MN_0B$  [18]. As the Shannon sampling theorem is respected, and by assuming  $s(t)$  limited in time and  $s_\tau(t)$  falling in the period of observation, we can write:

$$S_\tau[k] = \frac{S_\tau(f_k)}{T_s} = \frac{e^{-j2\pi f_k \tau} S(f_k)}{T_s} = e^{-j2\pi f_k \tau} S[k] \quad (2)$$

where  $S_\tau(f)$  and  $S(f)$  are the FTs of  $s_\tau(t)$  and  $s(t)$ , respectively, and  $S[k]$  is the DFT of  $s[m]$  and:

$$f_k = k/(MT_s) = k\Delta f. \quad (3)$$

For simplicity reasons, we denote from now  $S[k]$ ,  $R[k]$  and  $N[k]$  by  $S_k, R_k$  and  $N_k$ , respectively. From (1) and (2), we can write  $R_k$  as:

$$R_k = \alpha e^{-j2\pi(f_c + f_k)\tau} S_k + N_k = U_k + N_k \quad (4)$$

where  $U_k = \alpha e^{-j2\pi(f_c + f_k)\tau} S_k$  is the DFT of the useful part of the received signal. Denote by  $\rho_Z, \theta_Z, x_Z$  and  $y_Z$  the modulus, phase, real part and imaginary part of any complex number  $Z$ . From (4), we can define  $\phi_k$  as:

$$\phi_k = \theta_{S_k} - \theta_{U_k} = 2\pi(f_c + f_k)\tau. \quad (5)$$

Given that  $N_k$  is Gaussian, we can write the probability density function (PDF) of  $R_k$  as:

$$T_{R_k}(x_{R_k}, y_{R_k}) = \frac{1}{2\pi\sigma^2} e^{-\frac{(x_{R_k} - x_{U_k})^2 + (y_{R_k} - y_{U_k})^2}{2\sigma^2}} \quad (6)$$

$$T_{R_k}(\rho_{R_k}, \theta_{R_k}) = \frac{\rho_{R_k}}{2\pi\sigma^2} e^{-\frac{\rho_{R_k}^2 + \rho_{U_k}^2 - 2\rho_{R_k}\rho_{U_k}\cos(\theta_{R_k} - \theta_{U_k})}{2\sigma^2}}$$

where  $\sigma^2 = \sigma_N^2/2 = MN_0B$  is the variance of  $x_{N_k}$  and  $y_{N_k}$ .

## III. Statistics of the unwrapped MLE of the phase

In this section, we consider the MLE of the phase and compute the statistics of its unwrapped version.

The joint log-likelihood function of  $\rho_{U_k}$  and  $\phi_k$  can be obtained from (5) and (6):

$$\Lambda^{\rho_{U_k}, \phi_k} = -\frac{\rho_{R_k}^2 + \rho_{U_k}^2 - 2\rho_{R_k}\rho_{U_k}\cos(\theta_{R_k} - \theta_{S_k} + \phi_k)}{2\sigma^2}. \quad (7)$$

The CRLBs of  $\rho_{U_k}$  and  $\phi_k$  are the diagonal elements of the inverse of the Fisher information matrix given by  $-\mathbb{E}\{(\partial^2 \Lambda^{\rho_{U_k}, \phi_k} / \partial z_i \partial z_j)\}$ ,  $z_i, z_j \in \{\rho_{U_k}, \phi_k\}$  ( $\mathbb{E}\{\cdot\}$  denotes the expectation operator). The CRLB of  $\phi_k$  is given by:

$$C^{\phi_k} = \sigma^2 / \rho_{U_k}^2 = 1/\nu_k \quad (8)$$

where  $\nu_k = \rho_{U_k}^2 / \sigma^2 = \alpha^2 \rho_{S_k}^2 / \sigma^2$  is the SNR obtained at  $f_k$ .  $\nu_k$  is called the local (or instantaneous) SNR (corresponding to  $f_k$ ). The global SNR is defined as:

$$\nu = \sum_{k=-N/2}^{N/2-1} \nu_k. \quad (9)$$

It is obvious that the time delay can be estimated from an estimation of (5) as either: (i) the phase to angular frequency ratio or (ii) the slope of the phase with respect to the angular frequency. For both approaches, the estimated phase must be continuous. With the former it must also be around the true value, while with the latter a constant offset along the frequency axis is accepted. As in practice the phase is computed modulo  $2\pi$  (wrapped phase), an unwrapped version of it is needed in order to rebuild the continuous phase.

In practice, the unwrapped phase can be obtained recursively by adding a multiple of  $2\pi$  to the wrapped phase until the absolute difference between neighboring phases becomes less than or equal to  $\pi$ . Denote by  $\hat{\varphi}_k$  the wrapped MLE of the phase and  $\tilde{\varphi}_k$  the unwrapped MLE. We can write the unwrap criterion as:

$$|\tilde{\varphi}_k - \tilde{\varphi}_{k-1}| \leq \pi \quad (10)$$

where the non-ambiguity condition ( $2\pi\Delta f\tau < \pi$ ) must be respected. Unwrap procedure described above is well known and “unwrap” MATLAB function can be used to perform unwrapping.

As in practice the true value of the phase is unknown we can start the unwrap procedure from an arbitrary  $k_0$  by taking  $\tilde{\varphi}_{k_0} = \hat{\varphi}_{k_0}$ , then running the unwrap procedure for  $k_0 + 1, \dots, M/2 - 1$  and  $k_0 - 1, \dots, -M/2$ . It is obvious that the unwrapped phase may have an offset (almost constant  $\forall k$ ) with respect to the true phase dependent on the offset at the starting point ( $2\pi(f_{k_0} + f_c)\tau - \hat{\varphi}_{k_0}$ ).

Let us now consider how to obtain a wrapped estimation  $\hat{\varphi}_k$  of the phase. It can be obtained from (7) using a MLE and taking  $\partial A^{\rho_{U_k}, \varphi_k} / \partial \varphi_k = 0$ :

$$\hat{\varphi}_k = \theta_{S_k} - \theta_{R_k} = \theta_{S_k R_k^*}$$

where  $\{\cdot\}^*$  denotes the complex conjugate. The estimates  $\hat{\varphi}_k$  at different frequencies  $k$  are independent because the noise samples  $N_k$  are independent.

As shown in [19], the PDF of  $\hat{\varphi}_k$  can be obtained from that of  $\theta_{R_k}$  by integrating (6) with respect to  $\rho_{R_k}$ :

$$T_{\theta_{R_k}}(\theta_{R_k}) = \int_0^{+\infty} T_{R_k}(\rho_{R_k}, \theta_{R_k}) d\rho_{R_k} \Rightarrow$$

$$T_{\hat{\varphi}_k}^{wr}(\hat{\varphi}_k) = \frac{e^{-\frac{\nu_k}{2}}}{2\pi} + \frac{\sqrt{\nu_k} \cos(\hat{\varphi}_k - \varphi_k)}{2\sqrt{2\pi}} e^{-\frac{\nu_k}{2} \sin^2(\hat{\varphi}_k - \varphi_k)} \quad (11)$$

$$\times \operatorname{erfc}\left(\sqrt{\frac{\nu_k}{2}} \cos(\hat{\varphi}_k - \varphi_k)\right)$$

where  $\operatorname{erfc}(z) = (2/\sqrt{\pi}) \int_z^{+\infty} e^{-\xi^2} d\xi$  denotes the complementary error function, and the superscript “wr” the wrapped phase.  $T_{\hat{\varphi}_k}^{wr}(\hat{\varphi}_k)$  is  $2\pi$  periodic and can be defined on any interval ( $I_{c_k} = [c_k - \pi, c_k + \pi]$ ) of width  $2\pi$ .  $\int_{I_{c_k}} T_{\hat{\varphi}_k}^{wr}(\hat{\varphi}_k) d\hat{\varphi}_k = 1 \forall c_k$ . It is shown in [20] that the distribution of the wrapped phase can be approximated by a normal distribution if the local SNR  $\nu_k$  is sufficiently high, and by a uniform distribution if  $\nu_k$  is very low.

Let us now compute the PDF of the unwrapped MLE  $\tilde{\varphi}_k$  of the phase. Assume that we start the unwrap procedure from  $k = 0$  (so, we have  $\tilde{\varphi}_0 = \hat{\varphi}_0$ ). Let  $T_{\tilde{\varphi}_k}(\tilde{\varphi}_k)$  be the marginal PDF of  $\tilde{\varphi}_k$ . Below, we will show that  $T_{\tilde{\varphi}_k}(\tilde{\varphi}_k)$  can be computed recursively for  $k = 1, \dots, M/2 - 1$  and  $k = -1, \dots, -M/2$  starting from  $\hat{\varphi}_0$ .

As the unwrap criterion in (10) can be written as  $\tilde{\varphi}_k \in I_{\tilde{\varphi}_{k-1}} = [\tilde{\varphi}_{k-1} - \pi, \tilde{\varphi}_{k-1} + \pi]$ ,  $\tilde{\varphi}_{k-1}$  is then inside the domain  $D_k = [\min\{\tilde{\varphi}_{k-1}\} - \pi, \max\{\tilde{\varphi}_{k-1}\} + \pi]$ . As for  $\tilde{\varphi}_0 = \hat{\varphi}_0$  we have  $D_0 = [-\pi, \pi]$ , the domain  $D_k$  is given by:

$$D_k = [-|k+1|\pi, |k+1|\pi], (k = -N/2, \dots, N/2 - 1) \quad (12)$$

As  $\tilde{\varphi}_k \in I_{\tilde{\varphi}_{k-1}}$ ,  $|\tilde{\varphi}_k - \hat{\varphi}_k| = 2l\pi$  ( $l$  integer), and  $T_{\hat{\varphi}_k}^{wr}(\hat{\varphi}_k)$  is  $2\pi$  periodic, the conditional distribution of  $\tilde{\varphi}_k$  (PDF of  $\tilde{\varphi}_k$  given  $\tilde{\varphi}_{k-1}$ ) can be obtained from (11):

$$T_{\tilde{\varphi}_k | \tilde{\varphi}_{k-1}}(\tilde{\varphi}_k) = T_{\hat{\varphi}_k}^{wr}(\tilde{\varphi}_k).$$

Note that the domain of  $T_{\tilde{\varphi}_k | \tilde{\varphi}_{k-1}}(\tilde{\varphi}_k)$  depends on  $\tilde{\varphi}_{k-1}$  but not its expression. In order to express the marginal PDF of  $\tilde{\varphi}_k$  with respect to that of  $\tilde{\varphi}_{k-1}$ , we

first compute the joint PDF of  $\tilde{\varphi}_k$  and  $\tilde{\varphi}_{k-1}$ , and then we integrate with respect to  $\tilde{\varphi}_{k-1}$  taking into account that  $\tilde{\varphi}_k \in I_{\tilde{\varphi}_{k-1}}(\tilde{\varphi}_k - \pi \leq \tilde{\varphi}_{k-1} \leq \tilde{\varphi}_k + \pi)$ :

$$\begin{aligned} T_{\tilde{\varphi}_k, \tilde{\varphi}_{k-1}}(\tilde{\varphi}_k, \tilde{\varphi}_{k-1}) &= T_{\tilde{\varphi}_k | \tilde{\varphi}_{k-1}}(\tilde{\varphi}_k) T_{\tilde{\varphi}_{k-1}}(\tilde{\varphi}_{k-1}) \\ &= T_{\tilde{\varphi}_k}^{wr}(\tilde{\varphi}_k) T_{\tilde{\varphi}_{k-1}}(\tilde{\varphi}_{k-1}) \\ T_{\tilde{\varphi}_k}(\tilde{\varphi}_k) &= \int_{\tilde{\varphi}_k - \pi}^{\tilde{\varphi}_k + \pi} T_{\tilde{\varphi}_k, \tilde{\varphi}_{k-1}}(\tilde{\varphi}_k, \tilde{\varphi}_{k-1}) d\tilde{\varphi}_{k-1} \quad (13) \\ &= T_{\tilde{\varphi}_k}^{wr}(\tilde{\varphi}_k) \int_{\tilde{\varphi}_k - \pi}^{\tilde{\varphi}_k + \pi} T_{\tilde{\varphi}_{k-1}}(\tilde{\varphi}_{k-1}) d\tilde{\varphi}_{k-1} \end{aligned}$$

where for (13), we have  $\tilde{\varphi}_k \in D_k = [-|k+1|\pi, |k+1|\pi]$ . Finally,  $T_{\tilde{\varphi}_k}(\tilde{\varphi}_k)$  can be computed recursively for  $k = 1, \dots, M/2 - 1$  and  $k = -1, \dots, -M/2$  using (13). Obviously, the starting point is  $T_{\tilde{\varphi}_0}(\tilde{\varphi}_0) = T_{\tilde{\varphi}_k}^{wr}(\tilde{\varphi}_0)$ . The mean and the variance of  $\tilde{\varphi}_k$  are given by:

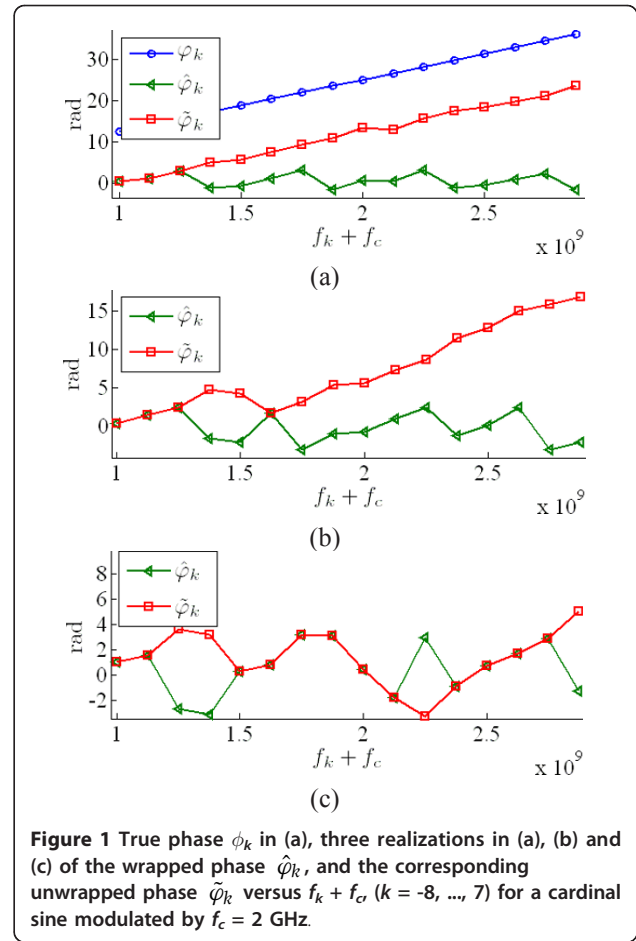

$$\mu_{\tilde{\varphi}_k} = \int_{-(k+1)\pi}^{(k+1)\pi} \tilde{\varphi}_k T_{\tilde{\varphi}_k}(\tilde{\varphi}_k) d\tilde{\varphi}_k \quad (14)$$

$$\sigma_{\tilde{\varphi}_k}^2 = \int_{-(k+1)\pi}^{(k+1)\pi} (\tilde{\varphi}_k - \mu_{\tilde{\varphi}_k})^2 T_{\tilde{\varphi}_k}(\tilde{\varphi}_k) d\tilde{\varphi}_k. \quad (15)$$

In Figure 1a, we show the true phase  $\phi_k$ , a realization of the wrapped MLE of the phase  $\hat{\varphi}_k (\hat{\varphi}_k \in [-\pi, \pi])$ , and the corresponding unwrapped MLE  $\tilde{\varphi}_k$  versus  $f_k + f_c$  (number of samples  $M = 16$ ,  $k = -8, \dots, 7$ ). The unwrap procedure is started here from  $k = -8$ . The transmitted signal is a cardinal sine (bandwidth  $B = 2$  GHz) modulated by a carrier ( $f_c = 2$  GHz). We take  $\tau = 2$  ns, and  $\nu = 17$  dB (global SNR). We can see that  $\tilde{\varphi}_k$  is almost continuous with a phase offset almost constant with respect to the true phase.

However, some errors multiple of  $-2\pi$  can be introduced during the unwrap procedure as can be seen in Figure 1b, c for two other realizations of the of the wrapped phase  $\hat{\varphi}_k$ . This happens when the unwrap procedure should add a multiple of  $2\pi$  to the next phase (for instance at  $k = -3$  in Figure 1b), but does not do it because the absolute difference between the neighboring noisy phases is less than  $\pi (|\hat{\varphi}_{-3} - \hat{\varphi}_{-4}| \leq \pi)$ . Every time this phenomenon happens, an additional error of  $-2\pi$  will be introduced.

Note that errors multiple of  $2\pi$  can also be introduced. This happens when the unwrap procedure should not add a multiple of  $2\pi$  to the next phase, but

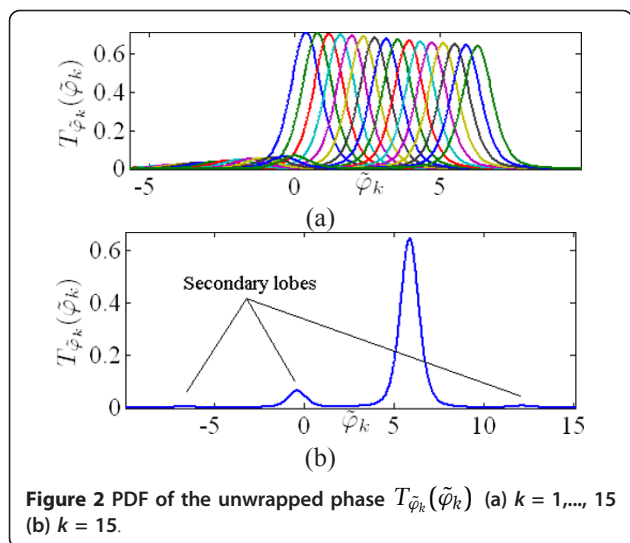

**Figure 1** True phase  $\phi_k$  in (a), three realizations in (a), (b) and (c) of the wrapped phase  $\hat{\varphi}_k$ , and the corresponding unwrapped phase  $\tilde{\varphi}_k$  versus  $f_k + f_c$  ( $k = -8, \dots, 7$ ) for a cardinal sine modulated by  $f_c = 2$  GHz.

does it because the absolute difference between the neighboring noisy phases is greater than  $\pi$ . These errors occur rarely if the slope of the true phase is positive.

In Figure 2a, b, we show the marginal PDF of  $\tilde{\varphi}_k$  for  $k = 1, \dots, 15$  and  $k = 15$ , respectively. We take  $B = 2$  GHz,  $f_c = 0$ ,  $\tau = 1$  ns,  $M = 32$ , and  $\nu_k = 5$  dB (local SNR),  $\forall k$ . Here we have started the unwrap procedure from  $k = 0$ . We can see in Figure 2b that for  $k = 15$  (phase corrected at the end of the unwrap procedure), the PDF has three secondary lobes located at  $-4\pi$ ,  $-2\pi$ , and  $2\pi$  from the main lobe. The strongest one is that located at  $-2\pi$ .

As already mentioned, the presence of these secondary lobes is due to errors multiple of  $\pm 2\pi$  introduced by the unwrap procedure. The main lobe becomes weaker and secondary lobes stronger as the frequency increases which means that we have more chance that such an error occurs. This is due to the fact that the unwrapping is performed recursively for increasing frequencies (see Figure 1a-c), so the  $\pm 2\pi$  errors accumulate over the course of the procedure. If we increase the number of samples or decrease the global SNR, we will obtain more secondary lobes at  $\dots, -4\pi, -2\pi, 2\pi, 4\pi, \dots$  from

the main lobe. Errors multiple of  $-2\pi$  (resp.  $2\pi$ ) are more frequent if the slope of the true phase is positive (resp. negative). Obviously, the unwrapped phase is biased, and both the bias and the variance increase with the frequency due to the accumulation of  $\pm 2\pi$  errors.

In Figure 3a, b, we show for the same scenario considered in Figure 2a, b the theoretical variance  $\sigma_{\tilde{\varphi}_k}^2$  and

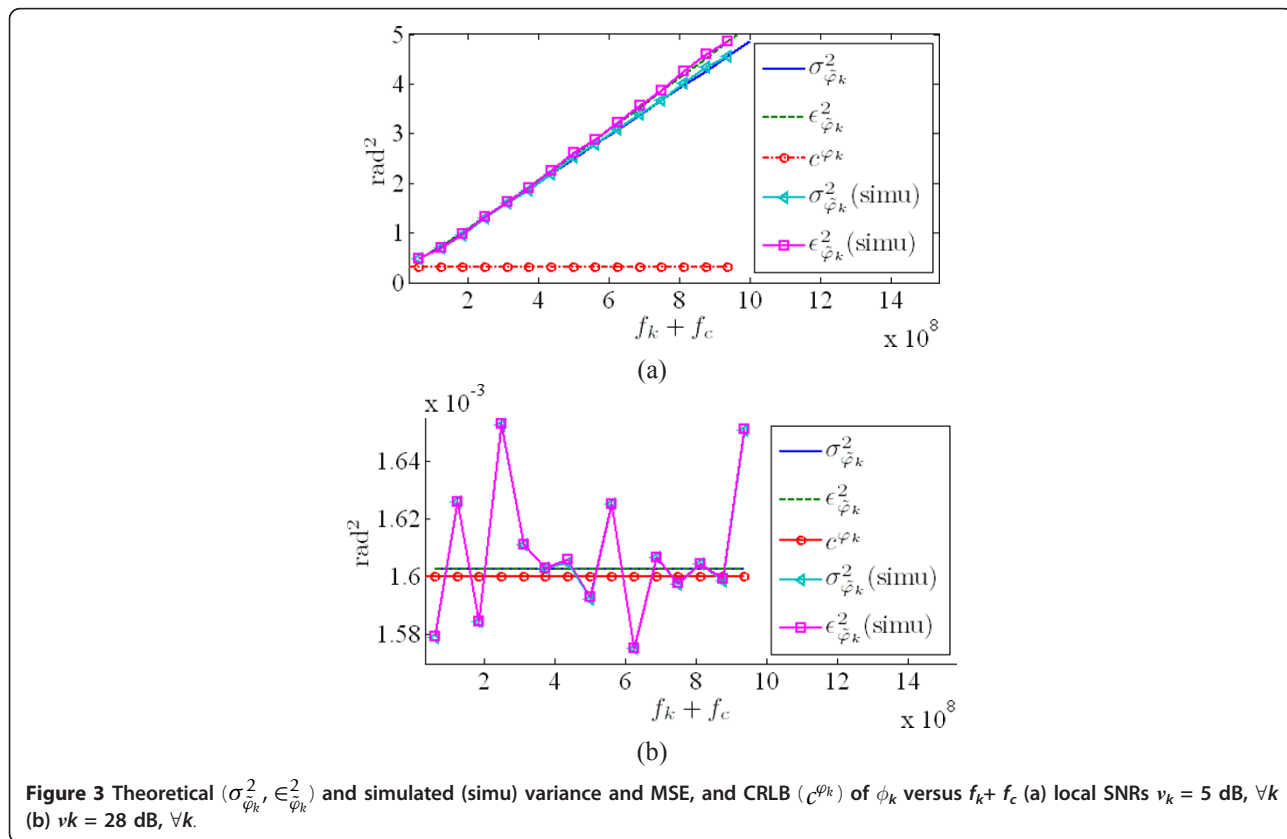

mean square error (MSE)  $\epsilon_{\tilde{\varphi}_k}^2 = \sigma_{\tilde{\varphi}_k}^2 + (\mu_{\tilde{\varphi}_k} - \varphi_k)^2$  (both computed from (14) and (15)), the CRLB  $c^{\varphi_k}$ , and the simulated (simulation repeated 10,000 times) variance and MSE of  $\tilde{\varphi}_k$ , all versus the frequency. For Figure 3a (resp. 3b), local SNRs are given by  $\nu_k = 5$  dB (resp. 28 dB),  $\forall k$ .

We can see in Figure 3a that the simulated variance and MSE closely follow the theoretical ones, which validates our theoretical approach. However, variance and MSE are not following the CRLB, and they increase with the frequency due to the errors multiple of  $\pm 2\pi$  which are introduced by the unwrap procedure.

In Figure 3b where the local SNRs are sufficiently high ( $\nu_k = 28$  dB,  $\forall k$ ), we can see that the derived and simulated variance and MSE are very close to the CRLB. In fact for high SNRs, the wrapped phases are unwrapped correctly because the errors multiple of  $\pm 2\pi$  become very rare.

#### IV. Slope-based and absolute-phase-based local TOA estimators

In the last section, we have studied the unwrapped MLE  $\tilde{\varphi}_k$  of the phase  $\phi_k$ . In this section, we propose two local TOA estimators based on  $\tilde{\varphi}_k$ .

In order to overcome the problem of the phase offset mentioned in subsection III, we define the first local estimator of  $\tau$  based on the slope of  $\tilde{\varphi}_k$ :

$$\tilde{\tau}_k^{bb} = \frac{\tilde{\varphi}_k - \tilde{\varphi}_0}{2\pi f_k}, k \neq 0 \quad (16)$$

where the superscript  $^{bb}$  denotes that  $\tau$  is estimated based on the information carried by the baseband frequency components.  $\tilde{\tau}_k^{bb}$  can be named either local slope-based or local baseband (BB) TOA estimator. By assuming (for simplicity reasons) that  $(\tilde{\varphi}_k)$  are independent (not true because of the unwrap procedure), the covariance and variance  $\sigma_{\tilde{\tau}_k^{bb}}^2$  of  $\tilde{\tau}_k^{bb}$  can be written as:

$$\Gamma(\tilde{\tau}_k^{bb}, \tilde{\tau}_{k'}^{bb}) = \begin{cases} \frac{\sigma_{\tilde{\varphi}_0}^2}{4\pi^2 f_k f_{k'}} & k \neq k' \\ \sigma_{\tilde{\tau}_k^{bb}}^2 = \frac{\sigma_{\tilde{\varphi}_k}^2 + \sigma_{\tilde{\varphi}_0}^2}{4\pi^2 f_k^2} & k = k' \end{cases} \quad (17)$$

In order to benefit from the information on  $\tau$  carried by the passband frequency components, and as the phase offset between  $\tilde{\varphi}_k$  and  $\phi_k$  is multiple of  $2\pi$ , we can estimate the phase offset by:

$$\tilde{\Delta\varphi} = 2\pi \text{round} \left\{ \frac{2\pi f_c \tilde{\tau}_k^{bb} - \tilde{\varphi}_0}{2\pi} \right\} \quad (18)$$

where “round” denotes the “round to nearest integer” function, and  $\tilde{\tau}_k^{bb}$  the global slope-based estimator.  $\tilde{\tau}_k^{bb}$  is given in Section V as a linear combination of  $\tilde{\tau}_k^{bb}$ .

As the phase offset is estimated, we can now define the second local TOA estimator from (5) and (18):

$$\tilde{\tau}_k^{pb} = \frac{\tilde{\varphi}_k + \tilde{\Delta\varphi}}{2\pi(f_k + f_c)} \quad (19)$$

where  $\tilde{\tau}_k^{pb}$  is named local absolute-phase-based or local pass-band TOA estimator. By assuming  $\tilde{\Delta\varphi}$  equal to the true value (true for high SNRs), the variance of  $\tilde{\tau}_k^{pb}$  can be written as:

$$\sigma_{\tilde{\tau}_k^{pb}}^2 = \frac{\sigma_{\tilde{\varphi}_k}^2}{4\pi^2(f_k + f_c)^2}. \quad (20)$$

The local passband CRLB of  $\tau$  can be obtained from (5) and (8):

$$c_k^{pb} = \frac{1}{4\pi^2 \nu_k (f_c + f_k)^2}. \quad (21)$$

If we assume in (5) that  $2\pi f_c \tau$  is a random phase (if phase uncertainty is introduced during the down-

conversion of the signal), the local baseband CRLB can be written as:

$$c_k^{bb} = \frac{1}{4\pi^2 \nu_k f_k^2}. \quad (22)$$

As for sufficiently high SNRs, the unwrapped phase becomes unbiased and its variance converges to its CRLB ( $1/\nu_k$ ), we can deduce from (20) and (21) (resp. (17) and (22)) that the local passband (resp. baseband) TOA estimator becomes also unbiased and achieves the local passband CRLB (resp. the sum of the local baseband CRLB of  $f_0$  and  $f_k$ ).

In Figure 4, we show the local baseband and passband CRLBs ( $c_k^{bb}, c_k^{pb}$ ), and the MSEs of the local baseband and passband TOA estimators ( $\epsilon_{\tilde{\tau}_k^{bb}}^2$  and  $\epsilon_{\tilde{\tau}_k^{pb}}^2$ ) obtained by simulation (noise generated 1,000 times), versus  $f_k + f_c$ . We consider a Gaussian pulse  $\exp(-2\pi t^2/T_w^2)$ ,  $T_w$  is the pulse width, modulated by  $f_c$ . We take  $T_w = 0.5$  ns,  $T_s = T_w/4$ ,  $f_c = 4$  GHz,  $\tau = 1$  ns,  $M = 32$  and  $\nu = 25$  dB. We can see that  $\tilde{\tau}_k^{pb}$  achieves the passband CRLB because the SNR is sufficiently high, while  $\tilde{\tau}_k^{bb}$  does not achieve the baseband CRLB. The gap between  $\epsilon_{\tilde{\tau}_k^{bb}}^2$  and  $c_k^{bb}$  corresponds to the term  $\sigma_{\tilde{\varphi}_0}^2/4\pi^2 f_k^2$  in the expression of  $\sigma_{\tilde{\tau}_k^{bb}}^2$  in (17).

## V. Slope-based and absolute-phase-based global TOA estimators

In this section, we derive the global TOA estimators based on the local TOA estimators studied in section IV.

The global baseband (resp. passband) TOA estimator  $\tilde{\tau}^{bb}$  (resp.  $\tilde{\tau}^{pb}$ ) is defined as the minimum-variance

Figure 4 Local baseband and passband CRLBs ( $c_k^{bb}, c_k^{pb}$ ), and MSEs ( $\epsilon_{\tilde{\tau}_k^{bb}}^2$  and  $\epsilon_{\tilde{\tau}_k^{pb}}^2$ ) of the local baseband and passband TOA estimators versus  $f_k + f_c$ .

unbiased linear combination of the local estimators  $\tilde{\tau}_k^{bb}, k = -M/2, \dots, M/2 - 1$  (resp  $\tilde{\tau}_k^{pb}$ ).

Consider  $M$  unbiased estimators  $\tilde{\zeta}_k$  of the same parameter  $\zeta$ . The minimum-variance unbiased linear combination of  $(\tilde{\zeta}_k)$  is given by:

$$\tilde{\zeta} = \tilde{\underline{a}}_{\tilde{\zeta}}^T \tilde{\underline{\zeta}}; \quad \left\{ \begin{array}{l} \tilde{\underline{a}}_{\tilde{\zeta}} = \underset{\underline{a}}{\operatorname{argmin}} \{ \sigma_{\underline{a}^T \tilde{\underline{\zeta}}}^2 \} \\ \text{s.t. } \sum \underline{a} = 1 \end{array} \right. \Rightarrow \tilde{\underline{a}}_{\tilde{\zeta}} = \frac{\underline{\Gamma}_{\tilde{\underline{\zeta}}}^{-1} \underline{1}}{\sum (\underline{\Gamma}_{\tilde{\underline{\zeta}}}^{-1} \underline{1})} \quad (23)$$

where  $\{\cdot\}^T$  denotes the transpose operator,  $\underline{z}$  the vector  $(z_1 \dots z_M)^T$ ,  $\sigma_{\underline{a}^T \tilde{\underline{\zeta}}}^2 = E\{(\underline{a}^T (\tilde{\underline{\zeta}} - \zeta \underline{1}))^2\}$ ,  $\sum \underline{a}$  the sum of the elements of  $\underline{a}$ ,  $\underline{1} = (1 \dots 1)^T$ , and  $\underline{\Gamma}_{\tilde{\underline{\zeta}}}$  the covariance matrix of  $\tilde{\underline{\zeta}}$ . The variance of  $\tilde{\zeta}$  is given by:

$$\tilde{\underline{a}}_{\tilde{\zeta}}^T \underline{\Gamma}_{\tilde{\underline{\zeta}}} \tilde{\underline{a}}_{\tilde{\zeta}}$$

From (17) and (23), we can obtain the global baseband estimator and its variance:

$$\tilde{\tau}^{bb} = \frac{(\underline{\Gamma}_{\tilde{\tau}^{bb}}^{-1} \underline{1})^T}{\sum (\underline{\Gamma}_{\tilde{\tau}^{bb}}^{-1} \underline{1})} \tilde{\tau}^{bb}; \quad \sigma_{\tilde{\tau}^{bb}}^2 = \tilde{\underline{a}}_{\tilde{\tau}^{bb}}^T \underline{C}_{\tilde{\tau}^{bb}} \tilde{\underline{a}}_{\tilde{\tau}^{bb}} \quad (24)$$

Given that the covariance matrix of  $\tilde{\tau}^{pb}$  is diagonal ( $\tilde{\tau}_k^{pb}$  assumed independent), we can write the global passband estimator and its variance as:

$$\tilde{\tau}^{pb} = \frac{\sum_{k=0}^{N-1} \tilde{\tau}_k^{pb} / \sigma_{\tilde{\tau}_k^{pb}}^2}{\sum_{k=0}^{N-1} 1 / \sigma_{\tilde{\tau}_k^{pb}}^2}; \quad \sigma_{\tilde{\tau}^{pb}}^2 = \frac{1}{\sum_{k=0}^{N-1} 1 / \sigma_{\tilde{\tau}_k^{pb}}^2} \quad (25)$$

As the covariances and variances of the local estimators  $\tilde{\tau}_k^{bb}$  and  $\tilde{\tau}_k^{pb}$  are unknown, we compute the global estimators from (24) and (25) by assuming that  $\tilde{\varphi}_k$  achieves the CRLB  $c^{\varphi_k}$ , and substituting  $\sigma_{\tilde{\varphi}_k}^2$  by  $1/\rho_{S_k}^2$  (proportional to  $c^{\varphi_k}$ ).

Given that  $N_k$  in (4) is a white sequence, the global passband and baseband CRLBs of  $\tau$  can be written as:

$$\begin{aligned} c^{pb} &= \frac{1}{\sum_k 1/c_k^{pb}} = \frac{1}{\sum_k 4\pi^2 \nu_k (f_c + f_k)^2} \\ &= \frac{1}{\nu (4\pi^2 f_c^2 + \beta_s^2)} \\ c^{bb} &= \frac{1}{\sum_k 1/c_k^{bb}} = \frac{1}{\sum_k 4\pi^2 \nu_k f_k^2} = \frac{1}{\nu \beta_s^2} \end{aligned}$$

where  $\nu$  is the global SNR given in (9) and  $\beta_s^2 = \sum_k 4\pi^2 \rho_{S_k}^2 f_k^2 / \sum_k \rho_{S_k}^2$  the discrete mean quadratic bandwidth of  $s[k]$ .

Let  $\tilde{\tau}^{ml}$  be the time-domain MLE of  $\tau$ .  $\tilde{\tau}^{ml}$  is given by:

$$\tilde{\tau}^{ml} = \underset{\zeta}{\operatorname{argmax}} \{r_{pb}(\zeta) \otimes s_{pb}(-\zeta)\}$$

where  $s_{pb}(t)$  and  $r_{pb}(t)$  denote the real passband transmitted and received signals and  $\otimes$  the convolution operator.

In Figure 5, we show the baseband and passband CRLBs ( $c^{bb}$  and  $c^{pb}$ ) of  $\tau$ , the MSEs ( $\epsilon_{\tilde{\tau}_k^{bb}}^2$  and  $\epsilon_{\tilde{\tau}_k^{pb}}^2$ ) of the global baseband ( $\tilde{\tau}^{bb}$ ) and passband ( $\tilde{\tau}^{pb}$ ) TOA estimators, and the MSE ( $\epsilon_{\tilde{\tau}^{ml}}^2$ ) of the MLE ( $\tilde{\tau}^{ml}$ ) versus the global SNR ( $\nu$ ). We consider a Gaussian pulse with  $T_w = 0.5$  ns,  $f_c = 4$  GHz,  $T_s = T_w/4$ ,  $\tau = 1$  ns, and  $M = 32$ . For the MLE, the sampling period must be smaller than the expected accuracy ( $T_s^{ml} \leq \sqrt{c^\tau}$ ). We

**Figure 5** Global baseband and passband CRLBs ( $c^{bb}$  and  $c^{pb}$ ), MSEs of the global baseband ( $\epsilon_{\tilde{\tau}^{bb}}^2$  and  $\epsilon_{\tilde{\tau}^{pb}}^2$ ) and passband ( $\epsilon_{\tilde{\tau}_k^{pb}}^2$  and  $\epsilon_{\tilde{\tau}_k^{bb}}^2$ ) estimators, and MSE ( $\epsilon_{\tilde{\tau}^{ml}}^2$ ) of the MLE versus the SNR ( $\nu$ ).

take  $T_s^{ml} = 1$  ps (125 times smaller than the DFT-based sampling period). The MSEs presented here are obtained by simulation (noise generated 10,000 times).

We can see that the global baseband estimator almost achieves asymptotically the baseband CRLB. We can also see that both the MLE and the global passband estimator achieve asymptotically the passband CRLB. However,  $\tilde{\tau}^{ml}$  achieves  $c^{pb}$  faster than  $\tilde{\tau}^{pb}$ . Many improvements can be introduced to our estimators in order to make them achieve the CRLBs faster. Hereafter, we will describe briefly one more baseband estimator and one more passband estimator.

We have already seen that the unwrap procedure introduces sometimes errors multiple of  $-2\pi$  in the unwrapped phase. These errors seriously deteriorate our estimators. In order to overcome this problem, we consider first the following slope-based estimator:

$$\tilde{\tau}_k^{sp} = \frac{\tilde{\varphi}_k - \tilde{\varphi}_{k-1}}{2\pi \Delta f} \quad (26)$$

where  $\Delta f$  is given in (3). The covariance  $\Gamma(\tilde{\tau}_k^{sp}, \tilde{\tau}_{k'}^{sp})$  and variance  $\sigma_{\tilde{\tau}_k^{sp}}^2$  of  $\tilde{\tau}_k^{sp}$  are given by:

$$\Gamma(\tilde{\tau}_k^{sp}, \tilde{\tau}_{k'}^{sp}) = \begin{cases} 0 & |k - k'| > 1 \\ -\frac{\sigma_{\tilde{\varphi}_k}^2}{4\pi^2 \Delta f^2} & k' = k + 1 \\ \sigma_{\tilde{\tau}_k^{sp}}^2 = \frac{\sigma_{\tilde{\varphi}_k}^2 + \sigma_{\tilde{\varphi}_{k-1}}^2}{4\pi^2 \Delta f^2} & k' = k \end{cases} \quad (27)$$

As the unwrapped phase errors described above generate large negative slopes, and as the time delay can be assumed positive by putting the reference pulse at the beginning of the observation period, we can mitigate these errors by keeping only the positive values of  $\tilde{\tau}_k^{sp}$ .

Let  $\tilde{\tau}_+^{sp}$  be the vector containing the positive values of  $\tilde{\tau}_k^{sp}$  and  $\underline{\underline{\Gamma}}_{\tilde{\tau}_+^{sp}}$  its covariance matrix.

A new global slope-based estimator can be obtained from (23) and (27):

$$\tilde{\tau}_+^{sp} = \frac{(\underline{\underline{\Gamma}}_{\tilde{\tau}_+^{sp}}^{-1} \underline{\underline{1}})^T}{\sum_{\tilde{\tau}_+^{sp}} (\underline{\underline{\Gamma}}_{\tilde{\tau}_+^{sp}}^{-1} \underline{\underline{1}})} \tilde{\tau}_+^{sp} \approx \frac{\sum_{\tilde{\tau}_k^{sp} > 0} \tilde{\tau}_k^{sp} \rho_{S_k}^2}{\sum_{\tilde{\tau}_k^{sp} > 0} \rho_{S_k}^2}. \quad (28)$$

Now, instead of unwrapping the phase recursively, we unwrap each  $\tilde{\varphi}_k$  (wrapped phase) with respect to  $2\pi(f_k + f_c)\tilde{\tau}_+^{sp}$  in order to get  $\tilde{\varphi}_k^{sp}$  (new unwrapped phase located around the true phase). The new global baseband (resp. passband) estimator  $\tilde{\tau}_+^{bb}$  (resp.  $\tilde{\tau}_+^{pb}$ ) is obtained as before from (16) and (24) (resp. (19) and

(25)), but after substituting  $\tilde{\varphi}_k$  by  $\tilde{\varphi}_k^{sp}$  (resp.  $\tilde{\varphi}_k + \tilde{\Delta}\varphi$  by  $\tilde{\varphi}_k^{sp}$ ) in (16) (resp. (19)).

The MSEs of  $\tilde{\tau}_+^{bb}$  and  $\tilde{\tau}_+^{pb}$  obtained by simulation are shown in Figure 5. We can see that  $\tilde{\tau}_+^{bb}$  and  $\tilde{\tau}_+^{pb}$  achieve  $c^{bb}$  and  $c^{pb}$  faster than  $\tilde{\tau}^{bb}$  and  $\tilde{\tau}^{pb}$ , respectively. Still, the MLE achieves  $c^{bb}$  and  $c^{pb}$  faster than  $\tilde{\tau}^{bb}$  and  $\tilde{\tau}^{pb}$ . However, for small SNRs ( $\rho < 15$  dB), the new passband estimator outperforms the MLE.

Finally, the main advantage of the MLE is that it achieves the CRLB faster, while the main two advantages of the new estimator are that: i) it requires a sampling rate and a number of samples much smaller than those required by the MLE and that ii) it outperforms the MLE for low SNRs.

## VI. TOA estimation in multipath channels

Assume now that we have a multipath UWB channel. The baseband channel impulse response can be written as:

$$h(t) = \sum_{l=1}^L \alpha^{(l)} e^{-j2\pi f_c \tau^{(l)}} \delta(t - \tau^{(l)})$$

where  $\alpha^{(l)}$  and  $\tau^{(l)}$  are the gain and the delay of the  $l$ th MPC. The baseband signal received through the multipath channel can be written as:

$$r_{MP}(t) = s(t) \otimes h(t).$$

Let  $\Gamma_{r_{MP},s}(t)$  be the cross-correlation function of the modulus of the baseband transmitted and received signals.  $\Gamma_{r_{MP},s}(t)$  can be written as:

$$\Gamma_{r_{MP},s}(t) = |r_{MP}(t)| \otimes |s(-t)|$$

where we have considered the modulus in order to get only one peak per MPC (the used baseband pulse must have only one lobe). The coarse estimates of  $\tau^{(l)}$  can be obtained as locations of the peaks of  $\Gamma_{r_{MP},s}(t)$  crossing a given threshold. Once the coarse estimates are obtained, we can apply our DFT-based estimators by taking a window around each MPC slightly larger than the pulse width. The final estimates of  $\tau^{(l)}$  are expected to have the same characteristics shown throughout this paper if the MPCs are not overlapping.

## VII. Conclusion

Two TOA estimators are proposed based on the absolute phase and the slope of the unwrapped phase of the DFT of the received signal. The slope-based TOA estimation is used as a coarse estimation in order to rebuild the absolute unwrapped phase and to compute the absolute-phase-based estimator. The statistics of the

unwrapped phase are computed. It has been shown that the slope-based estimator almost achieves asymptotically the baseband CRLB, while the absolute-phase-based estimator achieves asymptotically the passband CRLB. The proposed estimators are compared to the time-domain MLE estimator. It has been shown that the MLE achieves the CRLB faster than the DFT-based estimator, while the DFT-based estimator outperforms the MLE for low SNRs. It has also been also described how the proposed estimators can be used in multipath UWB channels. The main theoretical results are validated by simulation.
