(57) **ABSTRACT**

A system apparatus for controlling the whereabouts of an animal includes a receiver/stimulator unit affixed to the animal to selectively administer appropriate aversive stimuli effective to deter the animal from encroachment of boundaries in accordance with predetermined conditions based on radio signals received from at least one battery powered transmitter. The system may receive radio signals intermittently transmitted from the transmitter, the radio signals defining at least one boundary for the animal. The system then selectively administers the appropriate aversive stimuli in response to determining that at least one of the received radio signals satisfies one or more of the predetermined conditions.

BATTERY-POWERED RF SIGNALING SYSTEM AND SYSTEM FOR CONTROLLING THE WHEREABOUTS OF AN ANIMAL USING SAME

CROSS REFERENCE TO RELATED APPLICATIONS

[0001] This application is a continuation of application Ser. No.: 09/409,774 now U.S. Pat. No.: 6,166,643 which in turn is a continuation of application Ser. No. 08/956,732, now U.S. Pat. No. 6,064,038. U.S. Pat. Nos. 6,166,643 and 6,064,038 are both expressly incorporated herein by reference in their entireties to form part of the present disclosure.

[0002] A portion of the disclosure of this patent document contains material which is subject to copyright protection. The copyright owner has no objection to the facsimile reproduction by anyone of the patent document or the patent disclosure, as it appears in the Patent and Trademark Office patent file or records, but otherwise reserves all copyright rights whatsoever.

REFERENCE TO MICROFICHE APPENDIX

[0003] This disclosure includes a Microfiche Appendix containing computer program listings consisting in total of two (2) sheets of microfiche including one hundred thirteen (113) total frames which are expressly incorporated herein by reference in their entirety to form part of the present disclosure.

FIELD OF THE INVENTION

[0004] The invention relates to a novel, battery-powered RF signaling system and to systems for controlling the whereabouts of pets or other animals by using radio frequency transmissions to establish boundaries for animals and by applying stimuli to the animals when they move into proximity of such a boundary to deter them from traversing it. More particularly, the present invention relates to RF animal whereabouts control systems which are highly efficient, consume little power, exhibit excellent immunity to noise and signal propagation anomalies, permit different animals in the same vicinity to be subjected to different confinement conditions and are readily adaptable for use with new or preexisting wire loop boundary installations.

BACKGROUND OF THE DISCLOSURE

[0005] Traditionally, the whereabouts of animals have been controlled by erecting physical barriers such as walls, fences or gates at the site of a boundary the animal is to be prevented from crossing. Such barriers must not only be high enough to prevent the animal from jumping over and dense enough to prevent the animal from passing through any gaps but also substantial enough to withstand attempts by the animal to breach the barrier by physical force. The latter requirement is a serious limitation in that in addition to requiring considerable time and labor to erect, substantial physical barriers are often impracticable due to shortage of materials suitable for their construction.

[0006] Those limitations have been overcome to some extent by the development of avoidance-inducing physical barriers, of which, barbed wire and high voltage charged fences are well-known examples. Rather than relying solely on physical strength to defeat attempted breaches, animals quickly learn that contact with such barriers is associated with an aversive stimulus such as being shocked or pricked by sharp barbs. They therefore avoid repeated or sustained attempts to breach them. Physical barriers of the avoidance-inducing type have permitted the fencing of large areas with the expenditure of only a fraction of the time, effort and materials which had previously been necessary. However, avoidance-inducing physical barriers also suffer from some important limitations.

[0007] First, like all physical barriers, posts and wires or other above-ground structures are required to erect an avoidance-inducing physical barrier. In some applications, such as the confinement of household pets or guard dogs within a property line, these structures can be unsightly and are sometimes forbidden by deed restrictions or local regulations. Like all physical barriers, avoidance-inducing physical barriers are non-selective. A physical barrier sufficient to control the whereabouts of a particular animal also tends to impede the ingress and egress of persons or other animals except at locations where a gate may be provided. Moreover, the animal can traverse the barrier if the gate is inadvertently left open. Electrified or barbed wire fences intended for controlling the whereabouts of animals can also shock or injure persons, especially young children.

[0008] Various electronic systems which do not require the erection of above-ground barrier structures and which are at least somewhat selective in their operation are also known. In these systems, selectivity is achieved by equipping only the animal (or animals) whose whereabouts are to be controlled with an electronic unit capable of sensing when the animal moves into predetermined proximity of a defined boundary and then delivering one or more aversive stimuli to deter the animal from traversing the boundary. Such stimuli commonly comprise an electric shock either alone or in combination with an advance audible tone. A number of types of such electronic systems are known in the prior art. In most widespread use today are those of the "wire loop" type.

[0009] Various wire loop systems for controlling the whereabouts of animals are exemplified by U.S. Pat. No. 3,753,421 to Peck; U.S. Pat. No. 4,136,338 to Antenore; U.S. Pat. No. 4,733,633 to Yarnall, Sr. et al.; U.S. Pat. No. 4,745,882 to Yarnall, Sr. et al.; U.S. Pat. No. 4,766,847 to Venczel et al. and U.S. Pat. No. 4,967,695 to Giunta. In such systems, one or more continuous wire loops are routed along an arbitrary path to define a boundary. In some cases the wires are run above ground, in others they are buried. A controller connected directly to the loop generates an amplitude modulated (AM) signal which flows through the loop and causes an AM radio signal to radiate from the loop at a predetermined carrier frequency which is typically in the range of about 8 KHz to about 20 KHz. These systems operate by simple on/off keying. When a battery-powered receiver unit affixed to the animal receives an AM signal at a magnitude indicating close physical proximity of the animal to the boundary loop, the receiver initiates a generation of a tone and/or shock to deter the animal from crossing the loop. When an AM signal of such magnitude is not present at the receiver, no stimuli are applied to the animal.

[0010] Many AM wire loop systems which operate in this manner have been installed and are in operation at the present time. In certain of these systems, the animal's approach to the wire, as indicated by a received signal

strength above a predetermined threshold, initiates application of a first and relatively mild aversive stimulus (such as generation of a tone) which terminates if the animal retreats from the boundary. If on the other hand, the animal moves closer yet toward the loop, a higher threshold of signal strength is exceeded and a stronger aversive stimulus such as an electric shock is administered in order to repel the animal from the boundary as defined by the location of the wire.

[0011] The low RF frequency AM modulation used in prior art wire loop systems provides a number of advantages. Their low frequency AM radio signals propagate through soil well enough to provide acceptable signal range aboveground. Low frequencies are also less likely to reflect from non-metallic obstructions which might otherwise create "shadows" or gaps in the boundary field. Another advantage of low frequency AM modulation is that if the wire loop is inadvertently cut or breaks, the localized electrical field emitted across the break enables one to easily locate the break using an ordinary AM radio receiver. However, the low frequency AM wire loop boundary systems of the prior art also suffer from a number of disadvantages and limitations.

[0012] For example, AM systems are highly susceptible to electrical interference from a variety of common sources including motor vehicles, motor operated appliances, light dimmers, and television sets. Such interference can cause an animal to be shocked even when it is not near the boundary. This undesired shocking is not only unnecessary and inhumane if persistent, but can also confuse the animal and interfere with its being trained to associated the aversive stimulus with the intended boundary. In order to provide an acceptable margin against reception of false signals due to interference, AM systems of the prior art require a large received field intensity. Hence, the loop must be made to radiate a commensurately intense field.

[0013] Because a wire loop does not act as an efficient AM antenna at the low frequencies at which AM wire loop systems operate, a relatively large current, typically about two hundred (200) to about eight hundred (800) milliamps, must flow through the loop to generate a suitable boundary field. This not only consumes excessive power, making the system more expensive to operate but also precludes the possibility of powering the controller driving the loop using primary or backup batteries of reasonable size and cost. As a result, the controller must be mounted at a location, usually indoors, near an A.C. power outlet and an A.C. power outage renders the entire system inoperable. When this occurs, the entire boundary is breached not merely a localized portion of it making it much more likely that the animal will locate and exploit the breach. Also, since the closest point on the desired boundary may be some distance away from an available A.C. outlet, installation of wire loop systems is made more difficult, time consuming and expensive. The relatively large current flowing through the loop also creates a commensurately large low frequency electrical field. Some have suggested that such fields may pose health risks to humans or animals.

[0014] Installing the wire loop represents a substantial portion of the cost of a wire loop system. As noted above, a continuous length of wire must be run from the controller, around the desired boundary and back to the controller which is usually located at an indoor location remote from

any point on the desired boundary. The wire must be installed around or through any intervening walls or other obstacles. Even with special equipment built for the purpose, it is not a trivial task to bury a wire loop encompassing the perimeter of a large property. Installation is further complicated by the necessity of twisting the loop wires together wherever they must pass through locations where no boundary field is desired. Since the currents in any twisted portions of the wires flow in opposing directions, their fields cancel sufficiently that the unit affixed to the animal does not initiate application of an aversive stimulus even when the animal is nearby. Thus, by twisting portions of the loop together, a boundary located remotely from the controller and/or one having two or more distinct portions lying physically separated from one another can be formed using a single loop of wire connected to a single controller.

[0015] Remote broadcast systems are another class of electronic system known in the prior art for controlling the whereabouts of animals. These do not require installing a loop of wire to define a boundary. Instead, a boundary is established by broadcasting an RF signal from a central location toward an intended outer perimeter boundary. The location of the boundary is defined based on the strength of that broadcast signal as sensed by a unit affixed to the animal. For example, U.S. Pat. No. 5,067,441 to Weinstein describes an animal restraining system including a radio frequency transmitter, a transmitting antenna located inside an area in which the animal is to be restrained and a collar unit worn by the animal. A coaxial cable is run between the transmitter unit and the transmitting antenna. When the animal strays from the transmitting antenna a distance sufficient to permit the signal strength received by the collar unit to fall below a predetermined level, a first aversive of stimulus, such as a beeping tone, is generated. If the animal strays further from the antenna by a distance sufficient to cause the signal strength to fall below a second predetermined threshold, a stronger stimulus such as a shock is administered to the animal to deter its departure from the area. A similar system is described in U.S. Pat. No. 4,898, 120 to Brose.

[0016] A fundamental shortcoming of remote broadcast type systems for controlling animal whereabouts is that the collar unit worn by the animal does not detect proximity of the animal to a structure or object whose physical location reliably indicates the location of the intended boundary. Instead, such systems rely on measuring signal strength as an indicator of the distance the animal from a transmitting antenna which may be located a considerable distance from the boundary. Consequently, that indication is not always reliable. One reason is that because such systems operate in a far-field regime, the magnitude of the field decreases only in proportion to the square of distance from the transmitting antenna and does not vary significantly over distances on the order of several feet. Another reason is that the strength of the received signal can change due to constructive and destructive interference generated by signal reflections, shadowing by metallic objects and other uncontrollable variations in local reception conditions. Since local reception conditions can fluctuate, the size, shape and location of the boundary loci at which stimuli will be administered can also fluctuate. For example, if the signal path between the transmitting antenna is temporarily altered by an automobile which pulls into one's driveway, the animal may receive a shock even if the animal remains within an intended perim-

eter boundary. Remote broadcast systems also tend to require significant amounts of electrical power and thus, like wire loop systems, do not lend themselves to battery operation. This disadvantage stems in part from the need to broadcast a sufficiently strong signal to the most remote portion of the boundary and renders these systems, like AM loop systems, vulnerable to A.C. power failures.

[0017] Remote broadcast systems are also limited with respect to the sizes and shapes of perimeter boundaries they can define. While generally circular boundaries or ones conforming to the radiation pattern of a particular antenna can be implemented, continuous perimeter boundaries encompassing jutting regions or other well defined irregularities would be extremely difficult, if not impossible to establish using a remote broadcast type system. Another limitation of such systems is that because signal strength values are not unique to individual locations within the field of the transmitter, they are not well suited for excluding an animal only from arbitrarily located discrete positions, such as the site of one's prized rose bush for example. While wire loop systems offer greater flexibility and predictability of boundary shape, they are subject to the problems and limitations described above.

[0018] Another significant limitation of both the wire loop systems and the remote broadcast systems described above is that they are only capable of defining boundaries whose positions remained essentially fixed. Prior art U.S. Pat. No. 5,241,923 to Janning described for the first time an animal whereabouts control system which, while suitable for defining discrete and/or continuous fixed boundaries, was also capable of defining boundaries which moved with a mobile agent such as a child or another animal so that a particular animal such as a dog could be kept separated from child or other animal while otherwise allowing both dog and child complete freedom of movement. The systems described in Janning '923 operated at relatively high frequencies such as 915 Mhz where high antenna efficiencies could be obtained so as to reduce power requirements sufficiently to permit the system to operate on battery power. In such a system, individual active or passive high frequency transponders could be placed singly to exclude the animal from a specific location or arranged in mutually spaced arrays to form closed or partially closed continuous perimeter boundaries of virtually any desired size and shape. The transponders could be encapsulated for burial in the earth outdoors or packaged for placement beneath carpets, furniture cushions or area rugs or near entrances to rooms from which an animal was to be excluded.

[0019] Being of small size, light weight, and completely self-contained, the transponders disclosed in Janning '923 required no external wiring. Those transponders could also be provided with adhesive backing or with clips, pins or other attachment devices for securing them at a desired fixed location or to a mobile agent such as a child, an automobile or another animal which one might desire keeping separated from a particular animal. Using a collar or other suitable means of attachment, there could be affixed to the latter-mentioned animal a battery powered unit incorporating a receiver coupled to a stimulator for delivering a tone and/or a shock to the animal being controlled. Mounted either remotely or within the battery powered unit affixed to the controlled animal was a transmitter which generated an incident signal in the form of intermittent bursts of continu-

ous wave (CW) energy at 915 MHz. Upon receiving this incident signal, the transponders would generate a return signal. When the distance separating the animal from one of the transponders became sufficiently close, the return signal would be picked up by the receiver affixed to the animal and cause the stimulator to deliver an appropriate aversive stimulus. Optionally, one or more of the transponders could be provided with a delay line or surface acoustical wave device which could be used to encode the return signal so as to identify to the receiver the particular transponder from which the return signal is emanated so as to enable different animals to be subjected to different boundary constraints by a single system.

[0020] While representing a major breakthrough in the art due to their unprecedented flexibility, effective performance and simple, low-cost installation, systems for controlling animal whereabouts using transponders as disclosed in Janning '923 were subject to limitations. In particular, placement of transponders at certain locations, such as those adjacent or wholly or partially surrounded by metallic surfaces, sometimes resulted in blocked reflected or otherwise anomalous signal propagation manifested in undesired variations in distance sensitivity (i.e., boundary range) or the complete inability to establish an effective boundary at such locations.

[0021] Like all other known prior art systems (except for wire loop systems themselves), the systems described in Janning '923 also lacked the ability to function with a wire loop boundary. Accordingly, they could not be used to replace or upgrade existing AM wire loop systems of which, despite the disadvantages noted above, large numbers have been and continue to be installed in the field.

SUMMARY OF THE INVENTION

[0022] In view of the foregoing problems and limitations of the prior art, it is an object of the present invention to provide an RF signaling system capable of generating and broadcasting an RF signal with high energy efficiency.

[0023] It is another object of the invention to provide an RF signaling system which provides a high degree of immunity from noise and reception of false signals.

[0024] It is yet another object of the invention to provide a system for controlling the whereabouts of animals utilizing the RF signaling system of the invention to provide highly efficient operation affording long battery life.

[0025] A further object of the invention is to provide a system for controlling the whereabouts of animals in which the RF signaling system of the invention is adapted to provide extremely reliable data communications, even in the vicinity of metallic surfaces, with high immunity from noise and reception of false signals.

[0026] Another object of the invention is to provide a system for controlling the whereabouts of animals utilizing the efficient RF signaling system of the invention operating in a near-field regime to establish stable and distinct electronic boundaries which are unobtrusive, do not require the erection of physical barriers or other extensive installation, which may either be discrete or continuous in form and which may either be fixed or movable in location.

[0027] A further object of the invention is to provide a system for controlling the whereabouts of animals which

4

fulfills the foregoing objectives while being additionally capable of being used to establish a wire loop boundary in either new or preexisting wire loop installations and thus be capable of retrofitting, upgrading and/or expanding a wire loop boundary system easily and at low cost.

[0028] A further object of the invention is to provide a system for controlling the whereabouts of animals which is highly energy efficient permitting the entire system, including any wire loop boundary portions thereof, to operate for sustained periods entirely from battery power and thus remain fully effective in the event of an A.C. power outage.

[0029] A further object of the invention is to provide a system for controlling the whereabouts of animals which fulfills the foregoing objectives while facilitating location of the site of any break in a wire loop boundary using a conventional AM radio.

[0030] The invention provides an RF signaling system which operates with extremely high energy efficiency. In accordance with one important aspect of the invention, this is achieved by providing a transmitter with a resonant circuit, such as a tank circuit, which includes an antenna and which is tuned to resonate at a desired RF carrier frequency and by delivering to the antenna circuit a train of brief pulses of electrical energy repeated substantially at the aforementioned RF frequency. Upon delivery of each pulse, the antenna is caused to resonantly ring, thereby radiating energy in the form of an RF signal at the desired RF carrier frequency. The duration of each driving pulse is preferably as brief as possible to minimize damping of the antenna and thus, facilitate maximum radiation of RF energy. The duty cycle of the pulse train is ideally as small as possible while still providing pulses containing sufficient energy to deliver at the RMS RF power level required by a particular application. This duty cycle is preferably less than about five percent (5%) and is most preferably less than about one percent (1%). Where higher levels of transmitted power are required, the duty cycle of the pulse train may be increased at the expenses of some efficiency but should not exceed about fifteen percent (15%).

[0031] The invention is to be contrasted with prior art RF drive circuits would typically drive the output tank or antenna with an approximately 50% duty cycle (square wave). In such a case the output transistors of the drive circuit would be in conduction 50% of the time. If sinusoidal excitation were used, the output transistors could be in conduction up to 100% of the time. During such time, the output transistors would be loading the output tank with their output impedance, which could be quite low. In contrast, the present invention drives the output tank with very short pulses of current. The remainder of the time, the circuit is free to "ring" at its resonant frequency. This operation is analogous to striking a tuning fork or church bell with a clapper to make it "ring". If the clapper were held against the bell for a large percentage of the time, most of the acoustical energy would be dissipated by the clapper. Instead, a single impulse hit by the clapper is the most efficient way to generate the most sound with the least amount of input energy. Likewise in the present invention the "clapper" (current pulse) is of very short duration in order to increase the efficiency of radiated energy and greatly reduce the amount of energy dissipated by the drive transistors.

[0032] According to another important aspect of the invention, loading of the resonant circuit by the drive circuit which would otherwise damp the resonant ringing of the antenna and thereby decrease the energy efficiency of the system is substantially avoided by isolating the antenna circuit from the drive circuit during at least a portion, and preferably substantially the entirety, of the intervals between the driving pulses. This is achieved by providing an isolation circuit which is operably interposed between the drive circuit and the resonant circuit.

[0033] In the preferred embodiment, the isolation circuit is implemented using a pair of field effect transistors (FETs) connected mutually in parallel with one another between the drive circuit and the resonant circuit which includes the transmitting antenna. These FETs are selected to exhibit extremely low impedance when in conduction and thus facilitate delivery of high-current drive pulses to the resonant circuit with little forward loss. During the intervals between drive pulses however, both FETs are in a cutoff state in which they exhibit a nearly infinite output impedance. This serves to effectively decouple the resonating antenna from the drive circuit, thus electrically isolating the resonant circuit from any loading influence of the drive circuit.

[0034] The efficiency achieved by use of these aspects of the invention can be illustrated by considering for example an RF signal to be transmitted at ten kilohertz (10 KHz). A tank circuit including the antenna of the transmitter is tuned to resonate at 10 KHz. One microsecond high energy pulses are fed to the antenna at the desired RF frequency (i.e., a 10 KHz rate) from a drive circuit by way of an isolation circuit which exhibits a high output impedance during the intervals between pulses. Under such conditions, it can be appreciated that the circuitry driving the antenna draws current only 1% of the time (a 1% duty cycle). In contrast, a typical prior art system such as an AM system broadcasting at the same frequency with 100 Hz square wave modulation would draw current 50% of the time. The invention thus provides a comparative 50:1 reduction in drain on the battery or other power source supplying the transmitter thereby significantly increasing the ratio of radiated RF power to D.C. power consumed by the system. Because the drive circuit is effectively coupled to the antenna only during the brief intervals during which the drive pulses occur and is effectively decoupled therefrom during the overwhelmingly major portion of the cycle, the drive circuit loads the resonant circuit only for a correspondingly brief portion of the cycle. Thus, the invention not only draws less power but also permits the transmitting antenna to ring without being subjected to significant damping due to loading effects of the drive circuit in order to maximize the efficiency of the conversion of D.C. power to radiated RF power.

[0035] Other important aspects of the invention relate to systems for controlling the whereabouts of animals. In a preferred embodiment, the efficient RF signaling system of the invention is employed in a system using one or a plurality of small, battery-powered transmitters to transmit an RF signal establishing a boundary in the vicinity of the transmitter. A unit affixed to the animal includes a receiver capable of detecting the RF signal. Upon determining, based on information derived from the RF signal, that at least one predetermined condition indicating encroachment of the boundary has been satisfied, the unit delivers at least one aversive stimulus to the animal to deter such encroachment. These transmitters preferably utilize the RF signaling system

of the invention to provide extremely long operating life using a small, low cost battery.

[0036] As applied to such a system, the invention achieves even further improvements in energy efficiency by recognizing that an electronic boundary need not be present continuously without interruption in order to remain fully effective. According to this aspect of the invention, the RF signal establishing a boundary for the animal is interrupted by inactive intervals during which very little energy is consumed by the transmitter. In the preferred embodiment, the inactive intervals are in the range of about thirty to about one hundred milliseconds. However, for certain applications, particularly those involving indoor boundaries, much longer intervals, up to about five (5) seconds or longer can be used.

[0037] According to another important aspect of the invention, the transmitters operate in a near-field regime transmitting an RF signal whose magnetic field component is not only much larger than its electrical field component, but which also exhibits a magnetic field whose magnitude decreases substantially in proportion to the cube of increasing distance from the transmitter. To do so, the transmitters operate at a low frequency, preferably about ten kilohertz (10 KHz) or less and most preferably about eight point one nine kilohertz (8.19 KHz), and include a transmitting antenna which is electrically small. Because the magnitude of the detectable boundary field established by such an RF signal decreases so rapidly as distance from the transmitter increases, the boundary field is not only well localized, but is also sharply defined and therefore, positionally distinct. Moreover, because the field is predominantly magnetic in character and is established at such a low frequency, it is highly immune to blockage, reflections and distortion due to the presence of nearby metallic objects. These characteristics afford establishment of an electronic boundary capable of being detected positively, reliably and repeatably at a substantially unique locus of points in the vicinity of the transmitter. To even further enhance reliable detection of the RF signal, such as one defining an electronic boundary, a further aspect of the invention contemplates use of a modulation scheme in which the amplitude of the RF signal is bounded by an imaginary envelope of substantially constant magnitude at all times when the RF signal is actively transmitted.

[0038] Yet another object of the invention is to provide a system for controlling the whereabouts of animals in which a unit affixable to an animal is capable of administering an aversive stimulus in response to encroachment of a boundary established by RF signals emanating either from a wire loop or from one or more small, battery powered transmitters of the type referred to above. This is achieved by providing, in addition to such transmitters, a wire loop unit connectable to a wire loop whose path traverses the midst of a desired wire loop boundary. The wire loop unit excites the wire loop with radio frequency electrical energy and causes the wire loop to emit a constant envelope RF signal which the unit affixed to the animal can detect and respond to in the same manner as an RF signal emitted by any of the transmitters.

[0039] Since the RF signal which the wire loop unit generates and applies to a wire loop to establish a wire loop boundary is not an amplitude modulated (AM) signal, it

cannot be used to locate the site of a break in the wire loop. Accordingly, the wire loop unit includes circuitry which continuously monitors the continuity of the wire loop. In the event a break in the wire loop is detected, an audible and visible indication of the break is provided. At the same time, the wire loop unit decouples from the wire loop the RF signal which establishes the boundary and couples the wire loop to a source of amplitude modulated (AM) radio frequency electrical energy which enables one to locate the site of the break for repair purposes using a conventional AM radio receiver.

[0040] Another object of the invention is to provide a system for controlling the whereabouts of animals in which the RF signals referred to above are encoded such that the unit affixed to the animal can discriminate the boundary established by a wire loop from one established by any of the transmitters and/or can discriminate between the boundaries established by different ones of the transmitters. This enables different animals to be subjected to different boundary constraints and permits the form, intensity and/or other parameters associated with the stimulation delivered by the unit can be selected in accordance with the location of the particular boundary encroached upon by the animal.

[0041] According to the preferred embodiment, this is achieved by encoding the RF signals emanating from the wire loop as well as those emanating from each of the transmitters with an assignable digital code. The unit affixed to each animal to be controlled is programmed to determine whether or not to apply aversive stimulation when an RF signal is received from either the wire loop or one of the transmitters based on the particular digital code associated with that RF signal. By programming different ones of such units to respond to different Boolean combinations of these digital codes, different animals, even ones in the same general physical area, can be simultaneously subjected to different boundary constraints. The nature of the stimulation applied in response to reception of a particular digital code by a particular unit affixed to an animal can also be preprogrammed.

[0042] These and other objects and advantages of the invention will become apparent to the person of ordinary skill in the art upon review of the following detailed description of a preferred embodiment taken in conjunction with the appended drawings in which like reference numerals designate like items.

BRIEF DESCRIPTION OF THE DRAWINGS

[0043] FIG. 1 is a schematic diagram illustrating a preferred embodiment of a system for controlling the whereabouts of animals in accordance with the present invention in a typical installation.

[0044] FIG. 2A is a circuit schematic illustrating the electronic circuit of each of the transmitters shown in FIG. 1.

[0045] FIG. 2B is a continuation of the circuit schematic of FIG. 2A.

DETAILED DESCRIPTION OF A PREFERRED EMBODIMENT

[0061]   Referring to **FIG. 1**, there is illustrated an installed system **10** for controlling the whereabouts of an animal **12** according to the principles of the present invention in the vicinity of a dwelling **13** and surrounding areas. System **10** includes at least one receiver/stimulator unit **14** which may be mounted on a collar **15** or other suitable means of removably affixing unit **14** to animal **12**. System **10** further includes one or more small, lightweight battery powered transmitters **17**. Each transmitter **17** intermittently emits a digitally encoded, low frequency RF signal **18** capable of being received by receiver/stimulator unit **14** in order to establish an electronic boundary **20** which generally surrounds each transmitter **17**. Transmitters **17** are preferably packaged inside a sealed case of plastic or other suitable material and/or are potted to permit them to be used outdoors, either above ground or buried, as well as indoors. Transmitters **17** can be packaged and positioned in the same manner as taught with respect to the transponders described in commonly owned prior art U.S. Pat. No. 5,241,923 to Janning, which is expressly incorporated herein by reference in its entirety to form part of the present disclosure.

[0062]   According to the invention, system **10** also includes an optional wire loop unit **21** capable of being connected to a newly installed or preexisting wire loop **22**. Wire loop **22** acts as an antenna which emits a digitally encoded, low frequency, RF signal **18** generated by wire loop unit **21** for the purpose of establishing an electronic wire loop boundary **23** which generally surrounds wire loop **22**. While wire loop **22** is typically buried a few inches beneath the soil in order to provide for its concealment and mechanical protection, all or portions of it may be installed above ground, either indoors or outdoors, to establish one or more wire loop boundaries **23** of arbitrary size and shape in a desired location. Wire loop **22** may be twisted in the manner illustrated at area **26** in order to cancel the emitted field and thereby provide for desired discontinuities in wire loop boundary **23**.

[0063]   Animal **12** may roam freely unless and until it moves into sufficiently close proximity of either wire loop **22** or any of transmitters **17** as to enable receiver/stimulator unit **14** to detect the digital code associated with RF signal **18**. When this occurs, unit **14** determines whether one or more predetermined conditions associated with that code is satisfied. If no such condition is satisfied, unit **14** does not provide any form of stimulation and animal **12** remains free to roam about without being influenced by system **10**. If such a predetermined condition is satisfied however, unit **14** responds by administering one or more aversive stimuli to animal **12** to deter it from traversing the boundary **23** or **20** which has been approached.

[0064]   System **10** affords a high degree of flexibility in establishing effective boundaries of virtually any size, shape or location. Although capable of defining boundaries indoors and/or in relatively small areas, the use of a wire loop unit **21** in combination with a wire loop **22** is particularly well suited to the establishment of large outdoor boundaries such as one paralleling the perimeter of a property. By providing twisted areas such as the one illustrated in **FIG. 1** at area **26**, a wire loop boundary **23** located a considerable distance from wire loop unit **21** and/or one defining two or more distinct boundary areas physically separated from one another can readily be provided using a single wire loop unit **21** connected to a single wire loop **22**. Among other important distinctions over the prior art, the invention is novel in that the same receiver/stimulator unit **14** used to control the whereabouts of an animal **12** using a wire loop **22** can also be made responsive to the electronic boundaries **20** established by one or more discrete transmitters **17**. The ability to establish boundaries using discrete transmitters **17** alone or in combination with a new or preexisting wire loop **22** affords system **10** unprecedented flexibility permitting system **10** to replace, upgrade or expand prior art AM wire loop boundary systems at low cost and with minimal installation.

[0065]   As **FIG. 1** illustrates, transmitters **17** can be positioned at desired locations within a dwelling **13** or other structure so as to exclude animal **12** from specific locations therein, such as depicted at areas A and B which correspond, respectively, to the foot of a stairway **29** and the entrance of a room **30**. Other areas or items such as a rug or a piece of furniture may be similarly protected if desired. In addition or in the alternative, one or more transmitters **17** can be positioned to establish boundaries **20** at discrete fixed outdoor locations, such as the locations C and D indicated in **FIG. 1**. Such outdoor locations may correspond for example to a garden or outdoor dining area. Transmitters **17** can also be affixed to a mobile agent such as an automobile, another

animal or a child **31** which animal **12** is to be deterred from approaching. By placing a plurality of transmitters **17** in an open or closed array, such that at least a portion of the boundaries **17** associated with adjacent transmitters **17** at least partially overlap one another, continuous open or closed linear boundaries of virtually any desired shape and size, such as the linear boundary **33** illustrated in **FIG. 1** can also readily be formed for purposes of confining animal **12** within an area E such as a portion of a backyard. Animal **12** may thus roam freely within backyard area E inside of boundary **33** except for any locations where its passage may be forbidden by any boundaries **20** such as those established by the transmitters **17** present at locations C and D of **FIG. 1.**, or those attached to a child **31**.

[0066] System **10** affords further flexibility in that receiver/stimulator unit **14** can be configured in the field to select a type and intensity of stimulation most appropriate for a given animal **12**. The preferred embodiment for example can be configured to administer either an audible tone only or an audible tone in combination with either a less intense or more intense, yet harmless, electrical shock. For example, the receiver/stimulator unit **14** worn by animal **12**, which might be a large, aggressive animal, can be configured to administer a tone and a more intense electrical shock. System **10** can also include more than one receiver/stimulator unit **14** in order to control the whereabouts of a plurality of animals simultaneously. As **FIG. 1** illustrates, a second animal **12'** can be equipped with a second receiver/stimulator unit **14'** configured to administer only an audible tone or whichever of the other available types of aversive stimulation may be most appropriate considering the size and temperament of animal **12'**.

[0067] System **10** also affords flexibility in that it permits different animals to be subjected to correspondingly different boundary constraints. Different boundary constraints can be imposed not only to confine different animals to or exclude different animals from mutually separated areas but also to control the whereabouts of animals in physical areas which partially or entirely overlap. This is achieved by assigning each transmitter **17**, as well as optional wire loop unit **21**, with an identifiable code. This code is transmitted by way of RF signal **18** and used to determine the administration of aversive stimulation according to Boolean criteria applied by each particular receiver/stimulator unit **14** or **14'**.

[0068] By way of example, the system **10** of **FIG. 1** can be configured to confine animal **12** to area E, excluding it entirely from the interior of dwelling **13** as well as from child **31** and outdoor locations C and D. At the same time, second animal **12'** may be permitted contact with child **31** and allowed to roam freely anywhere within wire loop boundary **23** with the exceptions of room **30** and the second floor of dwelling **13**. This can be achieved in several different ways including by identifying the RF signals **18** emanating from wire loop unit **21** as well as those emitted by the transmitters **17** located at the foot of stairway **28** and the entrance of room **30** with an identical first code. The receiver/stimulator unit **14'** affixed to second animal **12'** is programmed to respond to that first code upon detection of same by administering an appropriate aversive stimulus to animal **12'** without responding to an RF signal **18** representing any other code. At the same time, all the other transmitters **17** of system **10**, including those on boundary **33**, those at locations C and D and the one affixed to child E,

emit an RF signal **18** encoded with a second code which is different from the first code. The above-described boundary constraints could then be achieved simply by programming the receiver/stimulator unit **14** worn by animal **12** to stimulate animal **12** only in the event the second code is detected. Preferably, however, unit **14** would also be programmed to likewise respond to detection of the first code. This would ensure that animal **12** would at least be confined within perimeter boundary **23** and would be excluded from room **30** as well as the second floor of dwelling **13** if animal **12** somehow escaped backyard area E. Under normal circumstances however, the transmitter **17** located at the northeast entrance of dwelling **13** and those forming linear boundary **33** would operate to exclude animal **12** from dwelling **13** entirely.

[0069] An important aspect of the present invention relates to a novel and improved radio frequency (RF) signaling apparatus and method which are incorporated in system **10** to establish highly energy efficient and reliable remote communication between transmitters **17** and receiver/stimulator unit **14** and/or **14'**. While described herein as applied to system **10**, those skilled in the art will appreciate that these aspects of the invention can be applied to great advantage in a wide variety of applications in addition to controlling the whereabouts of animals. Moreover, while disclosed herein as utilizing a particular form of constant envelope modulation known as binary phase shift keying (BPSK), those skilled in the art will readily appreciate that the invention can readily be implemented in forms utilizing other modulation schemes including without limitation other constant envelope modulation schemes such as pulse width modulation (PWM), minimum shift keying (MSK), and other forms of phase shift keying (PSK).

[0070] As noted above, each transmitter **17** intermittently transmits a digitally encoded RF signal **18** at a desired carrier frequency. In the preferred embodiment, RF signal **18** is preferably transmitted in a near-field regime using an antenna which is electrically small and transmitting at a low RF carrier frequency, preferably one of about 10 KHz or less, such as 8.19 KHz. This provides a number of important advantages. The field associated with an RF signal of such a low frequency in a near-field regime is predominantly magnetic rather than electric in nature and exhibits a magnetic field whose magnitude decreases in proportion to cube of distance (r^3) rather than the square (r^2) of distance from its source. This facilitates the establishment of electronic boundaries **20** which are both localized and positionally well-defined. The use of such a low RF frequency has also been found to afford high immunity to signal blockage, reflection and/or other signal propagation anomalies in areas adjacent to wholly or partially surrounded by metallic surfaces.

[0071] Referring to the circuit schematic of **FIG. 2**A and **FIG. 2**B, the structure and operation of a typical transmitter **17** will now be described. Transmitter **17** generates and transmits a digitally encoded RF signal **18** at an RF carrier frequency of 8.19 KHz with power derived solely from a small, long life lithium battery **36**. Each transmitter **17** includes a drive circuit **38**, a resonant circuit **40** and an isolation circuit **42** interposed between the drive circuit **38** and the resonant circuit **40**. Resonant circuit **40** includes a transmitting antenna **44** and preferably takes the form of a tank circuit tuned to resonate at the RF carrier frequency.

Antenna 44 includes a ferrite core 46 upon which is wound both a primary winding 47, terminating in a pair of leads 49 and 50, and a secondary winding 52, terminating in a pair of leads 54 and 55. Resonant circuit 40 consists further of a pair of capacitors 57 and 58 and a resistor 59, all connected mutually in parallel across secondary winding 46. For best efficiency, antenna 44 should have the highest possible quality factor, Q, and the overall Q factor of resonant circuit 40 is reduced as necessary by the loading effects of resistor 59 whose resistance is selected to provide a Q factor yielding the minimum bandwidth necessary to accommodate the data transfer rate required by a particular application. In the preferred embodiment, resonant circuit 40 has an overall quality factor of about forty three (Q=43).

[0072] Drive circuit 38 includes an oscillator circuit 61 which serves as a master clock. Oscillator circuit 61 includes a NAND gate, U6D, connected to a crystal 63 by way of resistors 64 and 65 and capacitors 66 and 67 as shown. Oscillator circuit 61 generates a 32.768 KHz master clock signal which is applied to the clock (CLK) input of a twelve stage ripple counter, U1. Ripple counter U1 serves as a frequency divider operable to generate several properly timed signals required by driver circuit 38.

[0073] Outputs Q11 and Q12 of ripple counter U1 are connected to respective inputs of a NAND gate U6A to provide, at output pin 3 thereof, a duty cycle control signal 70. According to an important aspect of the invention, inactive intervals are interposed between at least some and preferably each of the successive transmissions of RF signal 18. In the preferred embodiment, both the duration of each transmission of RF signal 18 and length of the inactive intervals between the intermittent transmissions of RF signal 18 are determined by duty cycle control signal 70. To minimize the drain on battery 36 and thus provide transmitters 17 with long operating life, duty cycle control signal 70 is timed to provide the shortest duration of individual transmissions of RF signal 18 and to maximize the inactive intervals between successive transmissions. In the preferred embodiment, duty cycle control signal 70 also serves to deactivate as much of the circuitry of transmitter 17 as possible during the inactive intervals between successive transmissions of RF signal 18 thereby enhancing the efficiency at which transmitter 17 converts D.C. power from battery 36 to useful radiated RF energy.

[0074] As illustrated in the timing diagram of FIG. 3, duty cycle control signal 70 takes the form of a periodic signal which assumes a low logic level for thirty-one and one-quarter milliseconds (31.25 mSec) and a high logic level for the remainder of its total period of one hundred twenty-five milliseconds (125 mSec). In the preferred embodiment, the 31.25 millisecond interval represents the maximum duration of each RF signal 18 while the remainder of the period (i.e., 93.75 milliseconds) corresponds to the inactive intervals between successive transmissions. The duration of the inactive intervals between successive transmissions of RF signal 18 is preferably maximized in order to maximize energy savings but is limited by the amount of time a particular boundary can remain inactive yet still be effective in a particular application. This will depend on a variety of factors such as the location of the boundary, the maximum expected speed of the animal in the vicinity of the boundary and the temperament of the animal. Preferably the inactive intervals between successive transmissions are selected to be

in a range from about thirty milliseconds (30 mSec) to about one hundred milliseconds (100 mSec) or more. Indeed, in the case of certain indoor boundaries, inactive intervals of up to about five seconds (5 Sec) or more may be suitable.

[0075] By establishing predetermined time intervals between transmissions of RF signal 18, duty cycle control signal 70 also plays an important role in avoiding the possibility of reception of false signals which might otherwise result in shocking animal 12 in error. As will be explained hereinafter, receiver/stimulator verifies reception of a valid RF signal 18 by requiring at least one subsequent RF signal 18 to be received within a limited time window occurring a predetermined time after an initial reception of RF signal 18. Preferably, the width of such a time window only slightly exceeds the duration of transmission of each RF signal 18 and begins at a time following reception of a prior RF signal 18 which is consistent with the duration of the inactive intervals between successive transmissions. If a subsequent RF signal 18 is not received within the predetermined time window receiver/stimulator unit 14 will not allow stimulation of animal 12 to occur.

[0076] Output Q6 of ripple counter U1 oscillates between high and low logic levels at 512 Hz and is connected to the input of pin 2 of an Exclusive OR gate U2A which serves as a buffer and an inverter by virtue of having a second input tied to the positive supply, +V. Output pin 3 of U2A provides a 512 Hz data clock signal 75. Ripple counter U1 also generates, by way of its output Q6, an RF carrier signal 80 which is applied to the input of a NAND gate U6C at pin 9 thereof. RF carrier signal 80 consists of a continuous stream of carrier pulses 82 occurring at a frequency of 8.19 KHz which corresponds as closely as possible to the resonant frequency of resonant circuit 40. NAND gate U6C includes a second input at pin 8 thereof. The input at U6C pin 8 is coupled to the output pin, pin 3, of NAND gate U6A by way of a NAND gate, U6B. NAND gate U6B has an input at pin 5 tied to the positive supply, +V, and a second input, pin 6, connected to pin 3 of NAND gate U6A to receive duty cycle control signal 70. NAND gate U6B inverts duty cycle control signal 70 thereby delivering to the input at pin 8 of a NAND gate U6C, a signal 83 which takes the form of 31.25 millisecond pulses occurring every 125 milliseconds. NAND gate U6B logically combines these pulses with the RF carrier signal 80 continuously present at its other input, U6C pin 9, in order to generate at its output, U6C pin 10, a signal 86 in the form of successive, 31.25 millisecond bursts of 8.19 KHz RF carrier signal repeated once every 125 milliseconds. Output pin 10 of NAND gate U6C, in turn, is connected to a first input at pin 5 of an Exclusive OR gate U2B whose operation will be explained shortly.

[0077] In order to provide RF signal 18 with an identifiable digital code as described above, the drive circuit 38 of each transmitter 17 includes a code generator 89. In the preferred embodiment, code generator 89 is implemented using a pair of 8-stage shift registers, U3 and U5 connected in cascade with one another. This is achieved by connecting the serial output, Q8 of shift register U3 to the serial input (SERIN) of shift register U5 and by connecting the serial output Q8 of shift register U5 to the serial input (SERIN) of U3. In order to minimize drain on battery 36 imposed by shift registers U3 and U5, duty cycle control signal 70 is applied to an ENABLE input at pin 9 of both shift registers U3 and U5. Doing so allows shift registers U3 and U5 to

operate and draw power only during the relatively short intervals when duty cycle control signal **70** is in its low logic state. Each shift register U3, U5 includes a clock (CLK) input which is tied to pin **3** of gate U2A in order to receive 512 Hz data clock signal **75** which controls the rate at which code data is delivered from code generator **89**.

[0078] Shift registers U3 and U5 also each include a respective series of eight inputs, identified as P11 through P18, which are selectively connected either to the positive supply voltage, +V, or to circuit ground in order to define an arbitrary **16** bit binary (four digit hexadecimal) digital code. In the particular transmitter **17** illustrated in **FIGS. 2A and 2B**, these inputs are configured to generate the hexadecimal code "F590." This is achieved by connecting inputs P18, P17, P16, P15, P13 and P11 of U5 and inputs P18, P15 of U3 all directly to the positive supply, while connecting inputs P14 and P11 of U5 and inputs P17, P16, P14, P13, P12 and P11 of U3 all directly to circuit ground. To facilitate assignment and/or changing of digital codes, one or more of the inputs P11 through P18 of shift registers U3 and/or U5 could alternatively be connected to the positive supply, +V, by way of high resistance pull-up resistors while being selectively connectable to ground by way of miniature switches, severable links or jumper wires. Such an arrangement would permit a single circuit board layout to be used to fabricate transmitters **17** capable of being identified by any of a number of different codes. It would also allow simple and rapid assignment or changing of codes in the field.

[0079] The operation of code generator **89** is such that each time data clock signal **75** undergoes a logic level transition during an interval when duty cycle control signal **70** is in a low logic state, individual binary bits of the assigned digital code are successively clocked out of the serial output Q8 of U5 as modulation data **92** as illustrated in **FIG. 3** beneath its corresponding hexadecimal representation **94**.

[0080] In order to modulate RF signal **18** with modulation data **92**, the serial output Q8 of shift register U1 is connected to a second input of Exclusive OR gate U2B at pin **4** thereof. As described above, Exclusive OR gate U2B includes a first input at U2B pin **5** which receives a 31.25 millisecond burst of 8.19 KHz RF carrier signal once every 125 milliseconds. Exclusive OR gate U2B operates as a binary phase shift modulator which mixes the RF carrier bursts appearing at U2B pin **5** with the modulation data **92** presented by code generator **89** at U2B pin **4**. In so doing, Exclusive OR gate U2B induces a phase shift of one hundred eighty degrees (180°) in the RF carrier whenever the modulation data **92** undergoes a logic level transition thus generating a binary phase shift keyed (BPSK) signal **96** at its output, U2B pin **6**. BPSK signal **96** takes the form of intermittent bursts **98** of binary phase shift-encoded carrier pulses **82** occurring nominally at the RF carrier frequency of 8.19 Khz. In accordance with duty cycle control signal **70**, each burst persists for no more than 31.25 milliseconds and repeats every 125 milliseconds The occurrence of the phase shifts of pulses **82** is indicated schematically in **FIG. 3** by the heavy vertical lines appearing at several points in BPSK signal **96**. A portion, indicated by reference numeral **100** in **FIG. 3**, of a typical one of such bursts at a typical data transition is illustrated in the expanded time scale timing diagram in **FIG. 4**. Additional reference will now be made to **FIG. 4** as the structure

and operation of the transmitter **17** circuit of **FIG. 2A** and **FIG. 2B** is further explained.

[0081] In order to adjust the range of RF signal **18** and thus the distance between each transmitter **17** and its associated electronic boundary **20**, transmitter **17** includes a variable time constant differentiator circuit **103**. Differentiator circuit **103** takes the form of a capacitor **105** and a variable resistor **106**. One side of capacitor **105** is connected to pin **6** of Exclusive OR gate U2B to receive BPSK signal **96** therefrom while its other side is connected to ground through variable resistor **106**. As **FIG. 4** illustrates, differentiator circuit **103** differentiates each of the carrier pulses **82** of BPSK signal **96** to generate a differentiated BPSK signal **108** characterized by sharply peaked pulses **110** which bear a fixed phase relationship to the corresponding carrier pulses **82** of BPSK signal **96**. While not shown in **FIG. 4**, peaked pulses **110** will actually be shifted in phase by a constant amount relative to carrier pulses **82**. That phase shift is immaterial however because it is constant. The peaks of differentiated BPSK signal **108** decay exponentially at a rate determined by the time constant of differentiator circuit **103** which can be adjusted by means of variable resistor **106**. Variable resistor **106** thus serves to adjust the amount of energy contained in pulses and thus, the effective range of transmitter **17**.

[0082] Differentiator circuit **103** is connected to the input of an Exclusive OR gate U2C at pin **10** thereof in order to apply differentiated BPSK signal **108** thereto. Exclusive OR gate U2C includes a second input at U2C pin **9** which is tied to the positive supply, +V. Exclusive OR gate U2C serves as a squaring amplifier which converts differentiated BPSK signal **108** into a BPSK driving signal **112** appearing at the output pin **8** of U2C. As shown in **FIG. 4**, BPSK driving signal **108** takes the form of a train of brief, rectangular, drive pulses **14** mutually separated by intervals **116** of time. Drive pulses **114** correspond in phase to peaked pulses **10** and thus repeat substantially at the RF carrier frequency of 8.19 KHz. By adjusting variable resistor **106**, the width of drive pulses **114** can be varied within a range from about seventy five nanoseconds (75 nSec) to about five microseconds (5 μSec).

[0083] When BPSK driving signal **112** is applied to resonant circuit **40**, it causes resonant circuit **40**, including antenna **44**, to resonantly ring thereby transmitting RF signal **18**. To minimize the damping effect of each drive pulse **114** on resonant circuit **40**, the invention contemplates that each drive pulse **114** be as brief as practicable while still containing a sufficient amount of energy to deliver the amount of radiated RMS power required by a particular application. Widening of drive pulses **114** any more than is necessary tends to increase their damping effect on resonant circuit **40** and thus decrease the efficiency at which transmitter **17** converts D.C. power to useful radiated RF power. In accordance with the invention, the duty cycle of BPSK driving signal **112** should be less than about fifteen percent (15%) and preferably less than about five percent (5%). Most preferably, BPSK driving signal **112** has a duty cycle of less than about one percent (1%). In the preferred embodiment, for example, the width of drive pulses **114** can be adjusted using variable resistor **106** such that the duty cycle of BPSK driving signal **112** ranges from about six hundredths of one percent (0.06%) to about four point one percent (4.1%).

[0084] In order to further enhance the efficiency of transmitter 17, a further aspect of the invention permits drive pulses 114 to be delivered at high current while minimizing any loading effects of drive circuit 38 which could otherwise damp the ringing of resonant circuit 40. To do so, the invention effectively electrically isolates drive circuit 38 from resonant circuit 40 during at least a portion, and preferably substantially the entirety, of the intervals 116 between drive pulses 114. This is done by operably interposing isolation circuit 42 between drive circuit 38 and resonant circuit 40.

[0085] In the preferred embodiment, isolation circuit 42 takes the form of a pair of DMOS field effect transistors (FETs) 120 and 121, each having respective gate (G), drain (D) and source (S) terminals connected mutually in parallel with one another as illustrated in FIG. 2B. The gates of FETs 120 and 121 are each connected to U2C pin 8 to receive BPSK driving signal 112. The output of isolation circuit 42 is coupled to resonant circuit 40 by connecting the common drains of FETs 120 and 121 to lead 49 of the primary winding 47 of antenna 44 and to ground by way of a clamping diode 123. The common source terminals of FETs 120 and 121 are connected to the positive supply, +V.

[0086] In operation, FETs 120 and 121 remain in a cutoff state until a drive pulse 114 of BPSK driving signal 112 is delivered to their gates from the output of Exclusive OR gate U2C. When a drive pulse 114 appears at their gates, FETs 120 and 121 are driven rapidly into full conduction providing a very low resistance current path from the +V supply to the primary winding 47 of antenna 44. In doing so, isolation circuit 42 allows driving pulses 114 to effectively be delivered to resonant circuit 40 at high current with very little forward loss. Current continues to be delivered to primary winding 47 until the present drive pulse 114 terminates. At that time, FETs 120 and 121 both abruptly enter a cutoff state in which substantially no conduction occurs. Clamping diode 123 serves to maintain this cutoff state during the entire interval 116 until the next successive drive pulse 114 occurs by blocking any voltages reflected to primary winding 47 due to ringing of the secondary winding 52 of antenna 44. FETs 120 and 121 remain in the cutoff state during each interval 116 between drive pulses 114 so that during intervals 116, isolation circuit 42 presents a substantially infinite impedance to resonant circuit 40 which prevents drive circuit 38 from loading resonant circuit 40 during intervals 116. In sum, isolation circuit functions essentially as a current amplifier in the form of a switch which closes to deliver the drive pulses 114 of BPSK driving signal 112 to resonant circuit 40 and which selectively opens during intervals 116 to avoid damping the ringing of resonant circuit 40 by drive circuit 48 during intervals 116.

[0087] In response to the delivery of the drive pulses 114 of BPSK driving signal 112 by way of isolation circuit 42, resonant circuit 40, including the secondary winding 52 of antenna 44, is caused to resonantly ring at the desired RF carrier frequency in the manner illustrated in FIG. 4 thereby transmitting a corresponding RF signal 18. Whenever the modulation data 92 generated by code generator 89 undergoes a data transition such as one as illustrated at reference numeral 100 in FIG. 3 and more clearly by the data transition indicated in FIG. 4, BPSK signal 96 undergoes a phase shift of one hundred eighty degrees (180°). This phase shift is reflected in differentiated BPSK signal 108, in BPSK driving signal 112 and ultimately in RF signal 18 as indicated. It is in this manner that the digital code provided by code generator 89 is ultimately imparted to RF signal 18.

[0088] As can be seen with reference to FIG. 4, RF signal 18 does not vary in amplitude as a result of its modulation. Instead, RF signal 18 is bounded by an imaginary envelope 125 of substantially constant magnitude. Use of such a "constant envelope" modulation scheme offers improved reliability over amplitude modulated (AM) communications by providing a signal which is always detectable at its maximum amplitude. Moreover, the energy efficiencies afforded by the invention are such that quiescent current consumption of the entire circuit of transmitter 17 at its minimum range setting is only 5.5 microamperes. A typical transmitter 17 constructed according to the preferred embodiment is capable of continuous operation for up to 7.7 years on a single 550 milliampere-hour battery 36.

[0089] Referring now to FIG. 5 and FIG. 6, the construction of antenna 44 will now be described in further detail. The secondary winding 52 of antenna 44 consists of one thousand thirty (1030) turns of #32AWG magnet wire wound around ferrite core 46 and terminating in secondary leads 54 and 55. Ferrite core 46 may suitably comprise one such as a part number 81400 available from Morely Transformer of Muncie, Ind. Ferrite core 46 has a magnetic permeability of eight hundred (800), an overall length of 3.1 inches and an elliptical cross section 0.5 inch wide with a maximum thickness of about 0.125 inch as illustrated in FIG. 6. Core 46 may suitably be fabricated from material designated SPX 4803000 available from National Magnetics Group of Bethlehem, Pa. or equivalent. As FIG. 5 shows, the central portion of secondary winding 55 is overlaid by primary winding 47 which consists of one hundred twenty five (125) turns of #32 AWG magnet wire terminating in primary leads 49 and 50. Primary winding 47 occupies the central 1.35 inches of secondary winding 52. In the preferred embodiment, antenna 44 has a quality factor, Q, of about eighty (Q=80).

[0090] Table 1 below is a parts listing for the transmitter circuit of FIGS. 2A and 2B.

TABLE 1

Reference	Description	Quantity	Manufacturer	Manufacturer's Part Number
106	100 Kohm variable resistor	1	Bourns Inc. (Riverside CA)	3352T-104-ND
44	antenna	1	see FIG. 5 & FIG. 6	
120, 121	−1.5V P channel DMOS FET	2	Zetex Inc. (Commack NY)	B5S84

TABLE 1-continued

Reference	Description	Quantity	Manufacturer	Manufacturer's Part Number
U1	12 stage ripple counter	1	National Semiconductor Corp. (Santa Clara CA)	CD4040BM
36	3 volt 500 mA hour lithium battery	1	Duracell USA (Bethel CT)	DL2450
123	diode, DL-35, SM	1	Diodes Inc. (Westlake Village CA)	DL4148
U6A–U6D	Quad NAND gate	1	Motorola, Inc. (Schaumburg IL)	MC14011UBD
U3–U5	8-stage shift register	2	Motorola, Inc. (Schaumburg IL)	MC14021BD
U2A–U2C	Quad Exclusive-OR gate	1	Motorola, Inc. (Schaumburg IL)	MC74HC86D
57	1000 pF, 0805 Pkg., 10%, capacitor	1	Surface Mountable Electronic Comonents, Inc. (Austin TX)	MCCE102K3NR-T1
67	20 pF, 0805 Pkg., 5%, capacitor	1	Surface Mountable Electronic Components, Inc. (Austin TX)	MCCE200J2NO-T1
66	5 pF, 0805 Pkg., 5%, capacitor	1	Surface Mountable Electronic Components, Inc. (Austin TX)	MCCE5R1D2NO-T1
105	68 pF, 0805 Pkg., 5%, capacitor	1	Surface Mountable Electronic Components, Inc. (Austin TX)	MCCE680J2NO-T1

59	16 Kohm, 0805 Pkg., 5%, resistor	1	ROHM Co., LTD. (Antioch TN)	MCR10-EZH-JW-163
64	470 Kohm, 0805 Pkg., 5%, resistor	1	ROHM Co., LTD. (Antioch TN)	MCR10-EZH-JW-474
58	0.01 μF, 0805 Pkg., 5%, plastic capacitor	1	NIC Components Corp. (Amityville NY)	NSPC103J50TRB2
63	32 KHz Crystal	1	Raltron (Miami FL)	R38-32.768 KHz

[0091] Receiver/stimulator units **14, 14'** operate to deliver an appropriate aversive stimulus in the event animals **12** or **12'** encroach upon an electronic boundary **20** or **23** defined by an RF signal **18** identified by modulation data **92** to which a particular receiver/stimulator unit **14, 14'** is programmed to respond. Each receiver/stimulator unit **14, 14'** includes a microprocessor based control and stimulation subsystem **130**, an RF receiver **133** and a quadrature demodulator **136** which are housed in a common housing secured to a collar for affixation to animal **12, 12'**.

[0092] Referring to **FIG. 7**, the structure and operation of the receiver **133** of a typical receiver/stimulator unit **14** will now be described. Receiver **133** as well as all other circuitry of receiver/stimulator unit **14**, are powered by a single replaceable battery **138** connected in parallel with a filter capacitor **139**. Battery **138** also supplies the operating power requirements of quadrature demodulator **136** and receiver **133**. In order to conserve battery **138**, the flow of operating current from battery **138** to the remainder of the circuitry of receiver **133** is controlled by means of a field effect transistor

(FET) **140** whose gate (G) is connected to an output line, CTL, of control and stimulation subsystem **130** which will be described in further detail below with reference to **FIG. 9**. A high resistance pull-up resistor **141** is connected between the gate and source terminals of FET **140**. FET **140** also includes a drain (D) terminal which is bypassed to ground through a capacitor **142**. The drain (D) of FET is connected to a positive supply rail **144** by way of a current limiting resistor **145** by way of a line **147** bypassed to ground through a capacitor **148**. Positive supply rail **144** is itself bypassed to ground by a pair of capacitors **149** and **150**. As indicated in **FIG. 7**, line **147** traverses an RF shield **152** which takes the form of an enclosure formed of copper sheet which encloses the circuitry indicated and serves to shield it from noise.

[0093] The circuitry of receiver **133** described thus far operates to selectively control the flow of electrical power from battery **138** to positive supply rail **144**. When the CTL line from control/stimulation subsystem **130** is in a low logic state, FET **140** is driven into conduction to provide a path for

delivering current from battery **138** to positive supply rail **144** by way of resistor **145**. When control and stimulation subsystem **130** drives its CTL line to a high logic state, FET **140** is rapidly cut off thereby blocking the flow of current from battery **138** to positive supply rail **144**. In the event of a failure in the control and stimulation subsystem **130**, pull-up resistor **141** serves to hold FET **140** in a cutoff state in order to conserve battery **138**.

[0094] In order to intercept an RF signal **18** when animal **12** encroaches upon either an electronic boundary **20** associated with a transmitter **17** or the wire loop boundary **23** emitted by wire loop **22**, receiver **133** includes an antenna **155**. Antenna **155** consists of a pair of mutually orthogonally positioned, twelve millihenry (12 mH) inductors **156** and **157**. Inductors **156** and **157** are connected electrically in parallel both with one another and with a series of parallel capacitors **158**, **159** and **160** and a resistor **161** to form a resonant front-end filter circuit **164**. Capacitors **158**, **159** and **160** are selected to resonate with inductors **156** and **157** at the RF carrier frequency of 8.19 KHz. Resistor **161** loads the resonant circuit in order to lower its quality factor, Q, to a value which widens its bandwidth sufficiently to pass the frequency components of interest associated with the modulation data **92** component of the RF signal **18** intercepted by antenna **155**.

[0095] Front end filter circuit **164** is connected to coupling capacitor **166** which delivers the RF signal **18** intercepted by antenna **155** to a class A, common emitter amplifier stage consisting of an NPN type bipolar junction transistor **169** connected in the conventional manner to the positive supply rail **144** and circuit ground by way of associated biasing resistors **171**, **172**, **173** and **174** as well as bypass capacitors **175** and **176** as shown. This first stage of amplification imparts a voltage gain of about twenty-nine decibels (29 dB) to the RF signal **18** presented by front end filter circuit **164**.

[0096] The collector of transistor **169** is connected by way of an a.c. coupling capacitor **180** to a second class A, common emitter amplifier stage consisting of an NPN type bipolar junction transistor **183**, associated biasing resistors **185**, **186**, **187** and **188** as well as bypass capacitors **189** and **190**. This second stage of amplification imparts an additional voltage gain of about twenty nine decibels (29 dB) to the RF signal **18**. In order to reduce the out-of-band noise which might otherwise cause a false indication that an appropriately encoded RF signal **18** has been received, the emitter of transistor **183** is connected to a resonant bandpass filter **191**. Filter **191** consists of an inductor **192**, a capacitor **193** and a capacitor **194** all of which are connected mutually in parallel between the emitter of transistor **183** and positive supply rail **144**. Filter **191** resonates at a center frequency of 8.19 KHz and is characterized by a quality factor, Q, of about four point four (Q=4.4) to provide a bandwidth of about 1.86 KHz.

[0097] Having been stripped of out-of-band noise by the action of bandpass filter **191**, RF signal **18** is amplified further. This is achieved by connecting the collector of transistor **183** by way of an a.c. coupling capacitor **197** to a third, and subsequently to a fourth, class A common emitter amplifier stage, each of which provides an additional voltage gain of about twenty-nine decibels (29 dB). The third stage consists of an NPN type bipolar junction transistor **200** connected conventionally to supply rail **144** and ground by

way of biasing resistors **203**, **204**, **205** and **206** and bypass capacitor **207**. The fourth amplification stage is connected to the collector of amplifier **200** by way of an a.c. coupling capacitor **210**. This fourth stage consists of an NPN type bipolar junction transistor **212**, connected in the conventional manner to supply rail **144** and ground by way of associated biasing resistors **215**, **216**, **217** and **218** and bypass capacitors **219** and **220** as shown.

[0098] A fully amplified rendition of the received RF signal **18** appears at the collector of transistor **212**. As a further precaution against an erroneous determination that a properly encoded RF signal **18** has been received, a D.C. offset voltage of about 0.53 Volts is imparted to this signal. This is achieved by connecting the collector of transistor **212** through an a.c. coupling capacitor **222** to the center of a voltage divider formed by a pair of resistors **224** and **225** connected in series with one another between positive supply rail **144** and circuit ground. The junction between resistors **224** and **225** is in turn connected to quadrature demodulator **136** by way of a current-limiting resistor **227**. Referring to **FIG. 8** the structure and operation of quadrature demodulator **136** will now be described.

[0099] Quadrature demodulator **136** is driven by a clock circuit **229** which generates a pair of 8.19 KHz signals **230** and **231** which are ninety degrees (90°) out of phase with one another. Clock circuit **229** includes a crystal **233** connected across an inverter U31 by way of a network consisting of resistors **236** and **237** and a capacitor **238** to form an oscillator which generates a free running 32.768 KHz signal at the output of U31A. The output of U31A is connected to the clock (CLK) input of a D-type flip-flop U33 A configured as a frequency divider. Flip-flop U33A has an output, Q at pin **1** thereof which provides a first 16.384 KHz signal. Flip-flop U33 A has a second output, Q̄, at pin **2** thereof which provides a second 16.384 KHz signal ninety degrees (90°) out of phase with aforementioned first 16.384 KHz signal. The output Q at pin **1** of flip-flop U33A is connected to the clock (CLK) input at pin **3** of a second flip-flop, U33B which is likewise configured as a frequency divider. Second flip-flop U33A includes an output Q̄, at pin **13** thereof which provides one of the aforementioned 8.19 KHz signals **230** which serves as a phase reference. In a similar fashion, the output Q at pin **2** of flip-flop U33A is connected to the clock (CLK) input at pin **3** of a third flip-flop, U35A, likewise configured as a frequency divider. Third flip-flop U35A includes an output Q at pin **1** thereof which provides quadrature 8.19 KHz signal **231**. Pin 13 of second flip-flop U33B is connected to pin 2 at the input of a first Exclusive OR gate, U36 A to deliver signal **230** thereto. Pin **1** of third flip-flop U35A is similarly connected to a corresponding input at pin **6** of a second Exclusive OR gate U36B to apply quadrature signal **231** thereto.

[0100] An inverter U31F includes an input which is connected to the resistor **227** of **FIG. 7** to receive an amplified and slightly D.C. offset rendition of RF signal **18** therefrom. Inverter U31F serves as a hard limiter which clips the peaks from the amplified RF signal **18** to generate a clipped BPSK signal **264**. The portions clipped away include any noisy portions thereof raised beyond the clipping threshold by virtue of the D.C. offset applied by the action of resistors **224** and **225** of **FIG. 7**. The output of inverter U31F is connected to the input at pin **1** of first Exclusive OR gate U36A as well as to the input at pin **5** of second Exclusive OR gate U36B.

Exclusive OR gates U36A and U36B serve to the clipped BPSK signal delivered at the output of U1F with phase reference signal 230 and quadrature signal 231. The outputs of Exclusive OR gates U36A and U36B are connected to respective low pass filters 267 and 268 which respectively consist of a resistor 270 and a capacitor 271 and a resistor 272 and a capacitor 273. Low pass filters 267 and 268 each have a −3 dB cutoff frequency of about 1 KHz thereby serving to recover from the clipped BPSK signal 26 both a code data signal 275 and a quadrature code data signal 276 which are buffered by respective inverters U31B and U31C connected to the output sides of low pass filters 267 and 26, respectively. The outputs of inverter U31B and U31C are connected to respective in-phase and quadrature (Q) inputs of the control and stimulation subsystem 130. Since the true phase of the clipped BPSK signal 264 is not known, either code data signal 275 or quadrature data signal 276 will faithfully represent the modulation data signal 92 shown in **FIG. 3** which identifies a particular transmitter 17 or, as will be explained hereinafter, wire loop 22.

[0101] Referring now to **FIG. 9**, control and stimulation subsystem 130 is powered entirely from battery 138 which is connected to a positive supply rail 283 by way of a current-limiting resistor 284. Power supply rail 283 is bypassed to circuit ground by way of a pair of capacitors 282 and 285. Subsystem 130 includes a programmed microprocessor 281 which receives operating power by virtue of connections to positive supply rail 283 and to circuit ground at pins designated VDD and VSS, respectively. Microprocessor 281 internally includes sufficient program memory and data memory as well as an arithmetic and logic unit, input/output facilities, a data bus, an address bus and other conventional timing and control facilities. Microprocessor 281 operates at a clock speed of 400 KHz established by a crystal 286 connected to an external oscillator input (OSC 2) at pin 15 of microprocessor 281 and to circuit ground by way of a pair of capacitors 287 and 288. A real time clock/counter (RTCC) input at pin 15 of the preferred microprocessor 281 identified in Table 2 below is not used and is tied to ground. Microprocessor 281 is programmed to have stored therein an operating program and certain data as set forth in detail in the relevant portions of the Software Appendix referred to above in order to control the operation of subsystem 130 in accordance with various inputs in the manner to be described. For that purpose, microprocessor further includes a plurality of bidirectional input/output (I/O) ports identified as RA0 through RA3 and RB0 through RB7. Individual ones of these ports are configured either as input ports or as output ports according to the stored operating program.

[0102] In order to allow microprocessor 281 to be programmed serially in the field, subsystem 130 includes programming port 291 physically accessible through the battery compartment of receiver/stimulator unit 14. Programming port 291 includes a series of three pins 292, 293 and 294 which may be used to program microprocessor 281 in the manner more fully described in programming specification DS30189 using hardware described in publication DS00589A, both of which are available from Microchip Incorporated of Dallas, Tex. and which are expressly incorporated herein by reference in their entirety to form part of the present disclosure. Pin 291 is connected to positive supply rail 283 by way of a pull-up resistor 296 as well as to reset pin 4 of microprocessor 281 while pins 293 and 294

are connected respectively to I/O ports RB6 at pin 6 and RB7 at pin 7 of microprocessor 281.

[0103] Receiver/stimulator units 14, 14 conserve battery 138 by selectively shutting down circuits which are non-essential at times when animal 12 is not moving. For that purpose, subsystem 130 is provided with a highly sensitive, single pole, single throw motion switch 299. One side of motion switch 299 is connected to circuit ground while its other side is connected to positive supply rail 283 by way of a voltage divider consisting of a resistor 300 and a resistor 301. To enable microprocessor 281 to read the state of motion switch 299, resistors 300 and 301 are connected at their common junction to an input port at RB5 at pin 11 of microprocessor 281. Motion switch 299 is mounted on the printed circuit board associated with subsystem 130 and opens and closes frequently when animal 12 is moving about. To selectively disable the battery conserving function associated with motion switch 299 for convenience in troubleshooting or testing system 10, one can install a jumper 304 to selectively tie I/O port RB0 at pin 6 to circuit ground. Port RB0 at pin 6 of microprocessor 281 is configured as an input port and is connected to positive supply rail 283 by way of a pull-up resistor 304 which acts to hold port RB0 at a high logic state at all times when jumper 304 is not installed, thereby enabling the battery conserving function associated with motion switch 299. That function is implemented using I/O port RA3 at pin 2 of microprocessor 281 which is configured as an output port and is connected by way of a resistor 306 to the control (CTL) input at the gate of FET 140 shown in **FIG. 7**.

[0104] When no jumper 304 is installed and animal 12 is determined by microprocessor 281 to be moving based on the inputs received from motion switch 299 by way of I/O port RB5, microprocessor 281 drives I/O port RA3 at pin 2 to a low logic level state thereby delivering operating power to receiver 133. Conversely, when the input received from motion switch 299 indicates animal 12 is not moving, there is no need for subsystem 130 to continue monitoring for encroachment of a boundary 20 or 23 as long as animal 12 remains not in motion. In that event, microprocessor 281 drive I/O port RA3 at pin 2 to a high logic level to cut off power to portions of circuitry of receiver 133.

[0105] To monitor the condition of battery 138, subsystem 130 includes a voltage detector 307 connected to positive supply rail 283 and circuit ground at pins 2 and 3 of detector 307, respectively. Voltage detector 307 includes an output pin, pin 1, which is connected to I/O port RB4 at pin 10 of microprocessor 283 which is configured as an input port. When power supply rail 283 drops to a voltage below a threshold of about 2.35 volts, pin 1 of voltage detector 307 undergoes a logic level transition which microprocessor 281 senses by sampling the signal at port RB4. To avoid the possibility of unpredictable operation in the event positive supply rail 283 drops below a second predetermined threshold voltage, a brownout protection circuit (not shown) may optionally be provided to reset microprocessor 281. Such a brownout protection circuit is described in detail in publication DS 30081B available from Microchip Incorporated of Dallas, Tex. which is expressly incorporated herein by reference in its entirety to form part of the present disclosure. A visible indication that battery 138 is in need of being replaced, subsystem 130 is provided by a light-emitting diode (LED) 308 whose cathode is connected to circuit

14

ground and whose anode is connected by way of a resistor **309** to port RA2 at pin **2** of microprocessor **281**. Port RA2 is configured as an output port which remains in a low logic state during normal operation. In the event the voltage on positive supply rail **283** drops below the threshold determined by voltage detector **307**, voltage detector **307** applies a signal to the input port RB4 of microprocessor **281**. In response to that signal, the operating program stored in microprocessor **281** toggles output port RA2 to blink LED **308** which is mounted so as to be visible exteriorly of receiver/stimulator unit **14**.

[0106] Control/stimulation subsystem **130** provides for the administration of various forms of aversive stimulation to an animal **12** in the event microprocessor **281** determines that an RF signal **18** satisfying one or more predetermined conditions has been received by receiver **133**. In order to permit such a determination to be made, the outputs of inverters U31B and U31C shown in **FIG. 8** are connected respectively to I/O ports RB2 and RB3 of microprocessor **281** at pins **8** and **9** thereof, respectively. Ports RB2 and RB3 are configured as input ports to enable microprocessor **281** to read code data signal **275** and quadrature code data signal **276**, respectively. The manner in which microprocessor **281** determines whether an RF signal **18** satisfying predetermined conditions has been received will be explained in further detail below with reference to the flowchart of **FIG. 15**.

[0107] In the preferred embodiment, stimulation can take the form either solely of a tone audible to animal **12** or as an audible tone and administered substantially simultaneously with a harmless electrical shock. The appropriate form and intensity of stimulation can be selected in accordance with the size and/or temperament of the animal **12** to be controlled. For example, a larger and/or more aggressive animal **12** can be administered a more intense ("High") shock of about five kilovolts (5 KV) in magnitude. Such "High" shocks preferably take the form of a thirty to ninety millisecond burst of individual pulses about six hundred microseconds (600 μSec) each in duration. A smaller and/or less aggressive animal **12'** can be administered only an audible tone or an audible tone combined with a less intense ("Low") shock of about two point five (2.5) kilovolts (2.5 KV) in magnitude. Such shocks preferably take the form of a series of individual pulses of about six hundred microseconds (600 μSec) each in duration. The form and intensity of stimulation is selectable in the field according to the position of a three position selector switch **310** having a movable wiper **314** one end of which connected permanently to circuit ground. Selector switch **310** further includes a series of terminals **311, 312** and **313**. Terminal **311** is connected by way of a resistor **305** to I/O port RB6 at pin **12** of microprocessor **281**. Port RB6 is configured as an input port and is connected to positive supply rail **283** by way of a pull-up resistor **302** which serves to maintain port RB6 at a high logic level except when wiper **314** is moved into contact with terminal **311**. When wiper **314** is moved into contact with terminal **311**, the voltage at port RB6 of microprocessor **281** drops to a low logic level. In a similar manner, terminal **313** of selector switch **310** is connected by way of a resistor **297** to I/O port RB7 at pin **6** of microprocessor **281**. Port RB7 is also configured as an input port and is connected to positive supply rail **283** by way of a pull-up resistor **298** (R28). Resistor **298** serves to maintain the voltage at port RB7 at a high logic level except when it is dropped to a low

logic level by moving the wiper **314** of selector switch **310** into contact with terminal **313**. Terminal **312** of switch **310** is open. Positioning of the wiper **314** of selector switch **310** at terminal **312** thus results in input ports RB6 and RB7 both remaining in a high logic level state.

[0108] The stored operating program causes microprocessor **281** to read the position of selector switch **310** to determine the appropriate form and intensity of stimulation to be delivered. To do so, microprocessor **281** reads the logic level states of inputs RB6 and RB7. If RB6 is determined to be in a high logic level state, the wiper **314** of selector switch **310** is determined to be in contact with terminal **310**. Microprocessor **281** is thereby instructed to administer stimuli in the form of both an audible tone and a "High" intensity electrical shock. When the wiper **314** of selector switch **310** is in contact with terminal **313**, port RB7 is determined to be in a low logic level state. This instructs microprocessor **281** that stimuli in the form of an audible tone and a "Low" intensity electrical shock are to be delivered. When microprocessor **281** determines that input ports RB6 and RB7 both remain at a high logic level, microprocessor **281** is instructed to administer stimulation only in the form of an audible tone. For administering electrical and audible stimuli, subsystem **130** includes both an audio transducer **315** and a pair of mutually spaced electrodes **316** and **317**.

[0109] Electrodes **316** and **317** preferably take the form of stainless steel pins about three quarters to about one inch in length and about one eighth of an inch in diameter. Each electrode **316, 317** has a respective distal end **318, 319** which is blunted to minimize discomfort and avoid irritation to the skin of animal **12**. Each electrode **316** and **317** has a proximal end **320, 321** which is preferably provided with a hexagonal head **322, 323** terminating in male threaded portion **324, 325** engageable with a threaded female socket **326, 327**. In this way, sets of interchangeable electrodes **316** and **317** of different lengths accommodating animals having coats of either short, long and medium length hair can be provided. Electrodes **316** and **317** are mounted to protrude normally from the surface of an injection molded housing mechanically affixed to animal collar **15**. This housing (not shown) includes a user accessible battery compartment to accommodate battery **138** and encloses all the remaining components of receiver/stimulator **14** including those of control and stimulation subsystem **130** as well as receiver **133** and quadrature demodulator **136**. Collar **15** holds electrodes **316** and **317** in sufficiently close contact with the skin of animal **12** to effectively administer electrical shock stimulation.

[0110] High voltage electrical shock pulses are generated by a step-up transformer **331** having a primary winding **332**, a magnetic core **333** and a secondary winding **334**. In the preferred embodiment, the primary to secondary turns ratio of transformer **331** is about 100:1. Secondary winding **334** is connected electrically in parallel across female sockets **326** and **327** in order to deliver high voltage shocks to animal **12** by way of electrodes **316** and **317**. One side of primary winding **332** is connected directly to the positive side of battery **138** while the opposite side of primary winding **332** is connected to the source terminal of a power MOSFET **336** the drain terminal of which is connected to circuit ground. In order to allow microprocessor **281** to selectively control the flow of current through primary

winding **332**, MOSFET **336** is connected at its gate terminal to I/O port RA0 at pin **17** of microprocessor **281** by way of a resistor **339**. Port RA0 of microprocessor **281** is configured as an output port.

[0111] When microprocessor **281** determines a shock is to be administered, mutually spaced bursts of appropriately timed, logic level, shock pulses **341** are generated by microprocessor **281** at output port RA0 as illustrated in **FIG. 10**. Each shock pulse **341** drives MOSFET **336** into conduction delivering a corresponding pulse of high current to primary winding **332** which drives transformer **331** into saturation. When each shock pulse **341** terminates, MOSFET **336** is rapidly cut off, abruptly terminating the flow of current through primary winding **332** resulting in generation of a high kickback voltage across secondary winding **334** and hence, electrodes **316** and **317**. The duration of each shock pulse **341**, the intervals between pulses **341**, the duration of each burst of shock pulses **341** and the intervals between such bursts are all determined by microprocessor **281** under program control.

[0112] For generating aversive audio stimuli, subsystem **130** includes an audio transducer **314** is connected electrically in series to circuit ground by way of a driver circuit **347**

which consist of a pair of FET's **349** and **350** connected mutually in parallel with one another as shown. The drains of FET's **349** and **350** are each connected to audio transducer **314** while their source terminals are each connected to the positive side of battery **138**. The gates of FET's **349** and **350** are connected directly to one another and are each connected to I/O port RA1 of microprocessor **281** by way of a resistor **351**. Port RA1 is configured as an output port which is normally maintained at a high logic level state by microprocessor **281** and pull-up resistor **352** connected between I/O port RA1 and positive supply rail **283**. This holds FETs **349** and **350** in a cutoff state preventing audio transducer **314** from sounding. When microprocessor **281** determines that an audio tone is to be delivered, microprocessor **281** generates an audio drive signal **353** by toggling output port RA1 at an audio rate, such as 3.2 KHz, in thirty to ninety millisecond bursts at mutually spaced intervals of about thirty milliseconds.

[0113] A parts listing for the circuitry of receiver/stimulator **14** including the receiver **133** of **FIG. 7**, the quadrature demodulator **136** of **FIG. 8** and the control and stimulation subsystem **130** of **FIG. 9**, is set forth below in Table 2.

[0114] As **FIG. 10** further illustrates, system **10** also permits aversive stimulation to be varied depending on the location of the boundary being encroached upon. The code generator **89** of each transmitter **17** can be configured as explained above to transmit an RF signal **18** bearing any one of nearly sixty five thousand unique digital codes. As will be explained shortly, a unique code can also be assigned to the RF signal **18** emitted by wire loop **22**. By assigning different codes to some or all of the transmitters **17** as well as the wire loop **22**, the wire loop boundary **23** can be distinguished from any of the electronic boundaries **20** associated with transmitters **17**. In addition, groups and/or individual ones of boundaries **20** can also be distinguished from one another as may be desired. The operating program associated with microprocessor **281** determines which particular one of a plurality of possible digital codes is represented by the code signal **275** and quadrature code signal **276** applied to input ports RB2 and RB3, respectively. Microprocessor **281** then drives output ports RA0 and/or RA1 in a particular preprogrammed manner which the operating program determines corresponds to a particular one of such codes. For example, it may be desired to deliver a stronger aversive stimulus in response to an encroachment of the perimeter wire loop boundary **23**. As **FIG. 10** illustrates, microprocessor **281** achieves this by delivering shock pulses **341** at port RA0 at a repetition rate of one shock pulse **341** about every seven point five milliseconds (7.5 mSec) in the event of encroachment of wire loop boundary **23**. In contrast, shock pulses **341** are delivered at intervals of twenty two point five milliseconds (22.5 mSec) in the event of encroachment of an electronic boundary **23** associated with a transmitter **17**. As **FIG. 10** further illustrates, the preferred embodiment of system **10** delivers audio stimulation in ninety millisecond (90 mSec) bursts when an electronic boundary **20** established by a transmitter **17** is encroached upon but in only thirty millisecond (30 mSec) bursts when wire loop boundary **23** is encroached upon. Preferably, such audio bursts are loud; on the order of about eighty decibels (80 dBA). Other alternatives are also possible. For example, to avoid disturbing the human occupants of dwelling **13**, microprocessor **281** can be programmed to provide audio stimulation of a form less noticeable to humans upon recognition of a digital code corresponding to one of the transmitters **17** located inside dwelling **13** such as those located at the foot of stairway **29** and/or the entrance to room **30**. This can be readily achieved by programming microprocessor **281** to provide an audio drive signal **353** consisting of fewer and/or shorter bursts and/or one at an elevated frequency inaudible to humans but capable of being heard by animal **12'**.

[0115] Microprocessor **281** is preferably programmed to strictly limit the amount of time any form of stimulation can be administered pursuant to any single boundary encroachment episode or series of episodes occurring very closely in time to one another. This can readily be done using a timer implemented in software or a counter which limits the number of times a stimulation loop is executed. This will ensure that the animal **12** will not be traumatized if for any reason the animal does not or is unable to promptly withdraw from a boundary **20** or **23** to terminate all stimuli by the animal's own volition. Microprocessor **281** is also preferably programmed to terminate all stimuli substantially immediately upon the withdrawal of the animal from a boundary **20** or **23**. Doing so not only serves to minimize any discomfort to animal **12**, but also helps avoid the possibility that the animal **12** will associate the stimulus with a behavior or condition other than its encroachment of the boundary **20** or **23**. Before explaining the operation of system **10**, and in particular the programming of microprocessor **281** in further detail, the structure and operation of wire loop unit **21** will now be described with reference to **FIG. 11** and **FIG. 12**.

[0116] Wire loop unit **21** includes a pair of five-way binding posts **360** and **361** connectable to opposite ends of wire loop **22** as shown. Wire loop unit **21** derives its normal operating power from an A.C. power outlet by way of a conventional step-down transformer which delivers 6 volts A.C. by way of a female plug connector (not shown) connectable to a mating male input jack **366**. Jack **366** is connected to a full wave rectifier **368** by way of a one-half ampere resettable fuse **369**. The D.C. output side of rectifier **368** establishes an unregulated 6 volt D.C. supply rail **370** which is connected in parallel with a filter capacitor **371** and a six volt battery **372**. Battery **372** which may suitably comprise a six volt gel cell type battery serves as a backup power source capable of operating wire loop unit **21** for sustained periods of time in the event of an A.C. power outage. The unregulated six volt D.C. supply rail **370** is connected in turn to the input of a five volt, voltage regulator **381**. The output side of five volt regulator **381** is paralleled with a filter capacitor **386** to establish a regulated five volt D.C. supply rail **388**.

[0117] A crystal **395** connected to a NAND gate U43A by way of a pair of resistors **397, 398** and a pair of capacitors **399, 400** generates a 32.768 KHz signal at the output of NAND gate U43A. The output of NAND gate U43A is connected to the input at pin **10** of a twelve stage ripple counter **402** as well as to the input at pin **8** of a NAND gate U43C and to the external oscillator input, OSC2 of a programmed microprocessor **404**. Ripple counter **403** operates as a frequency divider and includes an output, Q2 at pin

7, which provides a signal at the RF carrier frequency of 8.19 KHz. Ripple counter also includes an output, Q11 at pin 15 which generates a signal which oscillates at about 16 Hz and an output Q12 at pin 1 which oscillates at about 8 Hz.

[0118] Microprocessor 404 internally includes sufficient program memory and data memory as well as an arithmetic and logic unit, input/output facilities, a data bus, an address bus and other conventional timing and control facilities. Microprocessor 404 is connected between supply rail 388 and circuit ground by way of a pair of power supply inputs identified as VDD and VSS, respectively and includes a reset input at pin 4 which is tied to supply rail 388 by way of a resistor 405. Microprocessor 404 further includes a real time clock/counter (RTCC) input at pin 3 which is unused and is connected to circuit ground. Microprocessor 404 is programmed in the manner set forth in relevant portions of the Software Appendix and includes a set of four bidirectional input/output (I/O) ports located at pins 17, 14, 1 and 2 which are identified as ports RA0, RA1, RA2 and RA3, respectively. Ports RA0, RA1, RA2 and RA3 are each configured as input ports. Input port RA0 is connected to supply rail 388 by way of a pull-up resistor 406 and is also selectively connectable to circuit ground by way of switch 407 which forms part of a manually operable, quad, dual-inline-packaged (DIP) switch unit 408. In a similar fashion, output ports RA1, RA2 and RA3 of microprocessor 404 are connected to supply rail 388 by way of respective resistors 409, 410 and 411 and are selectively connectable to circuit ground by way of switches 412, 413 and 414, respectively. Microprocessor 404 also includes a pair of bidirectional input/output (I/O) ports configured as output ports: RB1 at pin 7 and RB2 at pin 8. Port RB1 is connected to a reset (RST) input at pin 11 of ripple counter 403. Output port RB2 is connected to an input pin, pin 1, of an inverter U42A as well as to the control input (E) at pin 5 of an analog switch U48A.

[0119] The positions of switches 407, 412, 413 and 414 of switch unit 408 control the logic level of the voltages at input ports RA0, RA1, RA2 and RA3. By reading states of those inputs, the operating program stored within microprocessor 404 determines which one of up to sixteen preprogrammed, sixteen bit (four digit hexadecimal) codes microprocessor 404 will repetitively present at output its port RB2. Each of these codes is analogous to the modulation data 92 delivered by the code generator 89 associated with each transmitter 17. In a manner which will be explained, the digital code presented at port RB2 of microprocessor 404 is imparted to the RF signal 18 emitted by wire loop 22 to permit receiver/stimulator unit 14 to distinguish wire loop boundary 23 from a boundary 20 established by a transmitter 17.

[0120] As the flowchart of FIG. 12 illustrates, microprocessor 404 reads input ports RA0, RA1, RA2 and RA3 immediately following power-up to determine the configuration of switch unit 408. Opening switches 407 and 414 while closing switches 412 and 413 cause microprocessor 404 to repetitively deliver the hexadecimal code "D9D9" at port RB2. Each bit of the code appears at port RB2 for about 1.953 mSec before being replaced by the next succeeding bit of the code. Thus, the entire sixteen bit code is presented over an interval of about thirty-one and one-quarter milliseconds (31.25 mSec). Once the entire code has been presented, port RB2 assumes a low logic level for an inactive interval of about thirty-one and one-quarter milli-

seconds (31.25 mSec) before repeating the code. This cycle repeats as long as wire unit 21 remains energized or until the configuration of switch unit 408 is changed. Alternatively, as FIG. 12 further shows, in the event switches 407, 412, 413 and 414 all in an open position, microprocessor 404 repetitively generates the hexadecimal code "F590" at output port RB2 once every one hundred twenty five milliseconds (125 mSec). Since the code itself is presented over an interval of thirty-one and one-quarter milliseconds (31.25 mSec), an inactive interval of ninety-three and three-quarters milliseconds (93.75 mSec) elapses before this code begins to repeat. Under such conditions, the output of port RB2 of microprocessor 404 is virtually identical to the modulation data signal 92 associated with one of transmitters 17 and the RF signal 18 emitted by wire loop 22 cannot be distinguished by receiver/stimulator unit 14 from a similarly encoded RF signal 18 emanating from a transmitter 17. This capability is useful in situations where it is not desired to distinguish wire loop boundary 23 from an electronic boundary 20.

[0121] As a convenient means of verifying the operability of wire loop unit 21, a special testing mode can be established by closing switch 414 of switch unit 408. Closing switch 414 causes the voltage at input port RA3 to assume a "high" or logic level "1" state. As FIG. 12 shows, microprocessor 404 reads port RA3 and determines whether or not it is in a high logic level state. If not, microprocessor 404 responds by determining further action based on the state of port RA0. If port RA3 is at a logic "1" state, however, microprocessor 404 responds by writing the hex code "D9D9" to output port RB2 three times only. Provided wire loop unit 21 and receiver/stimulator unit 14 are working properly, this results in delivery of a readily recognizable brief "burst" of audio stimulation from the audio transducer 315 of receiver/stimulator unit 14.

[0122] With reference once again to FIG. 11A and FIG. 11B, it can be seen that output Q2 at pin 7 of ripple counter 403 is connected by way of a resistor 421 to a tank circuit 422 which is coupled to ground by way of a capacitor 424. Tank circuit 422 is tuned to resonate at the RF carrier frequency of 8.192 KHz and consists of an inductor 426 connected in parallel with a capacitor 427. Tank circuit 422 resonates in response to the 8.192 KHz delivered from output Z2 at pin 7 of ripple counter 403 to generate a sinusoidal 8.192 KHz RF carrier signal 430.

[0123] Wire loop unit 21 modulates RF carrier signal 430 according to the digital code generated at output port RB2 at pin 8 of microprocessor 404 using binary phase shift keying. To do so, wire loop unit 21 is provided with an inverter U42A, and a pair of amplifiers U44A and U44B whose outputs are connected respectively to the line side (Y) of a pair of analog switches 433 and 434, respectively. Tank circuit 422 is connected as shown to the noninverting input of amplifier U44B which is configured as a unity gain buffer by virtue of a connection between its output and its inverting input. The output of amplifier U44B thus delivers a sinusoidal RF carrier signal at zero phase shift (ϕ=0°) to the line side (Y) of analog switch 433. In a complementary fashion, a sinusoidal RF carrier signal at a relative positive phase shift of ninety degrees (ϕ=+90°) is delivered to the load side (Y) of analog switch 434. This is achieved by connecting tank circuit 422 by way of a coupling capacitor 436 and a resistor 437 to the noninverting input of amplifier U44A. Amplifier U44A has its inverting input connected to the

center of a voltage divider formed of a pair of resistors **439** and **440** connected in series with one another between supply rail **388** and circuit ground to establish an offset voltage for amplifier U44A. Amplifier U44A is configured as a unity gain, inverting amplifier by virtue of a resistor **441** connected between its output and its non-inverting input as shown. The output of amplifier U44A thus delivers to the line side (Y) of analog switch **434** a sinusoidal RF carrier frequency signal bearing a positive ninety degree phase shift to the corresponding signal present at the line side (Y) of analog switch **433**. Analog switches **433** and **434** operate as normally open relays which close in response to application of a logic level signal at their respective control inputs (E) which are located at pins **5** and **13** of switches **433** and **434**, respectively.

[0124] In order to generate a BPSK signal modulated with the code generated at output port RB2 at pin **8** of microprocessor **404**, port RB2 is connected directly to the control input (E) at pin **13** of analog switch **434** and is connected by way of an inverter, U42A to the control input (E) at pin **5** of analog switch **433**. Inverter U42A serves to ensure that analog switches **433** and **434** are never both open or both closed at the same time. When the code signal appearing at output port RB2 at pin **8** of microprocessor **404** is at a low logic level (i.e., data bit=0), analog switch **434** opens and analog switch **434** closes. This causes the RF carrier signal at zero degrees phase shift ($\phi=0°$) to be applied to the load side (Z) of analog switch **433**. Conversely, when the code signal appearing at output port RB2 at pin **8** of microprocessor **404** is at a high logic level (i.e., data bit=1) analog switch **433** opens and analog switch **434** closes. This causes the RF carrier signal at a positive ninety degree phase shift ($\phi=+90°$) to be applied to the load size (Z) of analog switch **434**.

[0125] To facilitate adjustment of the effective range of the RF signal **18** emitted by wire loop **22** and thus, the effective width of wire loop boundary **23**, wire loop unit **21** includes a potentiometer **444** which is connected to a limiting resistor **445** as shown. Resistor **445** is connected at a summing junction in series to the load side (Z) of analog switch **434** by way of a coupling capacitor **447** and a series resistor **448**. Resistor **445** is similarly connected in series with the load side (Z) of analog switch **433** by way of a coupling capacitor **449** and a series resistor **450**. The common connection point of resistors **448** and **450** defines a summing junction **451** at which the outputs of analog switches **433** and **434** are effectively summed to define an 8.192 KHz sinusoidal BPSK signal whose instantaneous phase is correlated to the digital code repetitively presented at output port RB2 of microprocessor **404**. By adjusting potentiometer **444**, the amplitude of the BPSK signal applied to the wiper of potentiometer **444** from summing junction **451** by way of resistor **445** can be adjusted.

[0126] The wiper of potentiometer **444** is connected to the load side (Y) of an analog switch **453** whose load side (Z) defines a node **455**. In normal operation, analog switch **453** remains closed so long as wire loop **22** remains continuous thereby delivering the aforementioned BPSK signal to node **455**. Node **455** is in turn connected to the non-inverting input of an amplifier U47 by way of a coupling capacitor **459**. The output of amplifier U47 is connected in series with wire loop **22** by way of a coupling capacitor **461** and a current limiting resistor **462**. Resistor **462** is connected to the

binding post **360** connected to one end of wire loop **22**. The opposite end of wire loop **22** is connected to circuit ground by way of binding post **361**. A metal oxide varistor **464** is connected between binding post **360** and circuit ground to protect wire loop unit **21** from any high voltage transients which might be picked up by wire loop **22** in the event of a lightning strike. Amplifier U47 serves to amplify the sinusoidal BPSK signal whose instantaneous phase varies in accordance with the code data generated by microprocessor **404** at output port RB2. This amplified BPSK signal is then applied to wire loop **22** which serves as a transmitting antenna which broadcasts this digitally encoded BPSK signal as an RF signal **18**. While the RF signal **18** emitted by wire loop **22** has a continuous sinusoidal component, the encoded portion thereof continuously repeats following brief delay intervals of about thirty-one and one-quarter milliseconds (31.25 mSec). When potentiometer **444** is set such that RF signal **18** has a range establishing a wire loop boundary **23** extending radially from wire loop a distance of about six feet, an RMS current of only about thirteen milliamperes flows through wire loop **22**. Adjusting potentiometer **444** to increase that distance to about twenty feet requires an RMS current of only about forty-four milliamperes. This contrasts very favorably to the AM wire loop boundary systems of the prior art in which currents on the order of about eight hundred milliamperes were required to be circulated through a wire loop to establish an AM boundary field extending radially six to eight feet from the wire loop. Due to the dramatic reduction in operating current required using the invention, back-up battery **372** allows wire loop unit **21** to operate and wire loop boundary **23** to be maintained fully effective for sustained periods of time in the event of an A.C. power failure.

[0127] The continuity of wire loop **22** is monitored by a break detector circuit **466** which is connected to wire loop **22** by way of a diode **468** whose cathode is connected to binding post **360** and whose anode is connected to the center of a voltage divider consisting of a pair of resistors **469** and **470**. Resistor **469** serves as a pull-up resistor and is connected to positive supply rail **388** as shown. As long as wire loop **22** remains continuous, the anode of diode **468** remains at a voltage only slightly above circuit ground. In the event wire loop **22** breaks however, the voltage at the anode of diode **468** rises to charge a capacitor **471** which is connected in series between resistor **470** and circuit ground.

[0128] The voltage across capacitor **471** is monitored by an operational amplifier U44C configured as a comparator. The non-inverting input of amplifier U44C is connected to the positive side of capacitor **471** by way of a resistor **473** and is connected to the output of amplifier U44C through a feedback resistor **475**. The inverting input of amplifier U44C is connected to the center of a voltage divider consisting of a pair of resistors **477** and **478** connected in series with one another between supply rail **388** and circuit ground as shown. Resistors **477** and **478** serve to maintain the inverting input of amplifier U44C at a predetermined threshold voltage. Amplifier U44C continuously compares that threshold voltage to the voltage at its non-inverting input to define a break indicating signal at a "BREAK" terminal **480** at the output of amplifier U44C. In normal operation, wire loop **22** remains unbroken and the voltage across capacitor **471** remains sufficiently below the constant threshold voltage at the inverting input of amplifier U44C to cause amplifier U44C to hold the voltage at BREAK terminal **480** at a low

logic level voltage. In the event the electrical continuity of wire loop **22** is broken however, the voltage at the non-inverting input of amplifier rises sufficiently to cause the output amplifier U44C at BREAK terminal **480** to assume a high logic level voltage.

[0129] Wire loop unit **21** includes an audio transducer **483** and a light emitting diode (LED) **484** which provide audible and visual indications, of a break in wire loop **22**. For that purpose, BREAK terminal **480** is connected by way of a resistor **485** to the inverting input of an amplifier U44D. The non-inverting input of amplifier U44D is connected to a voltage divider network consisting of a pair of resistors **486** and **487** and a capacitor **488** connected as shown between supply rail **388** and circuit ground to establish a threshold voltage. The inverting input of amplifier U44D is also connected to the 8 Hz output Q12 at pin **12** of ripple counter **403** by way of a resistor **490**. The output of amplifier U44D is connected to the inputs of a pair of hysteresis inverters U42B and U42C whose outputs are paralleled with one another and connected to the input of audio transducer **483**. The outputs of inverters U42B and U42C are also connected to the inputs of a second pair of inverters U42F and U42D whose outputs are likewise paralleled and connected by way of a current limiting resistor **493** and LED **484** to circuit ground.

[0130] Provided loop wire **22** remains continuous, the voltage at the inverting input of amplifier U44D always remains below the threshold voltage applied to its non-inverting input. However, in the event of a break in wire loop **22**, the voltage at BREAK terminal rises. The voltage at the non-inverting terminal of amplifier U44D is then biased sufficiently to cause the output of amplifier U44D to toggle at an 8 Hz rate. Driving amplifiers U42B, U42C and U42F, U42D cause audio transducer **483** to sound and LED **484** to flash at a corresponding rate to audibly and visibly signal the breakage of wire loop **22**.

[0131] Since it is not an AM signal, the RF signal **18** normally emitted by wire loop **22** cannot be detected by a conventional AM radio to locate the site of a break in wire loop **22**. To permit a user to locate a break in wire loop **22** using an AM radio, wire loop unit **21** includes facilities for selectively applying an AM signal to wire loop in the event such a break is detected by break detector **466**. For this purpose, wire unit **21** includes a NAND gate U43C having a first input connected to BREAK terminal **480**. NAND gate U43C includes a second input connected to the output of NAND gate U43A to receive the 32.768 KHz signal described above. The output of NAND gate U43C is thus normally at a constant low logic level state but oscillates at the rate of 32.768 KHz in the event BREAK terminal **480** assumes a high logic level due to a break in wire loop **22**. The output of NAND gate U43C is connected to a first input of a NAND gate U43B. NAND gate U43B also includes a

second input which is connected to output Q11 at pin **15** of ripple counter **403** to receive the 16 Hz signal described above. Consequently, the output of NAND gate U43B will normally remain in a constant low logic level state but will take the form of bursts of 32.768 oscillations repeating at a 16 Hz rate in the event BREAK terminal **480** assumes a high logic level indicating a break in wire loop **22**. It will immediately be recognized that the pulsating 32.768 KHz signal generated by NAND gate U43B in the event of a break in wire loop **22** constitutes a 32.768 KHz AM signal at one hundred percent (100%) modulation.

[0132] The output of NAND gate U43B is connected by way of a coupling capacitor **495** to the center of a voltage divider consisting of a pair of resistors **496** and **497** connected in series with one another between positive supply rail **388** and circuit ground. Resistors **496** and **497** serve to apply a 2.5 volt D.C. offset to the AM signal delivered from the output of NAND gate U43B. The junction between resistors **496** and **497** is connected to the line side (Y) of an analog switch **499**. Analog switch **499** includes a control terminal (E) which is connected directly to BREAK terminal **480**. The load size (Z) of analog switch **499** is connected to node **455**. The control terminal (E) of analog switch **453** is connected to BREAK terminal **480** by way of an inverter U42E. Since the voltage at BREAK terminal **480** remains in a low logic level state as long as wire loop **22** remains continuous, analog switch **499** normally remains open while inverter U42E apples a high logic signal to the control input (E) at pin **8** of analog switch **453** thereby maintaining analog switch **453** closed as described earlier. Under such normal operating conditions, analog switch **453** serves to apply the BPSK signal received by the wiper of potentiometer **444** by way of resistor **445** from node **451** to amplifier U47 which serves to deliver an amplified BPSK signal to wire loop **22** which emits a correspondingly encoded RF signal **18**.

[0133] In the event of a break in wire loop **22**, however, BREAK terminal assumes a high logic level which causes analog switch **453** to open thereby terminating the application of the amplified BPSK signal to wire loop **22**. At substantially the same time analog switch **453** opens, analog switch **499** closes thus delivering the AM signal described above to node **455**. This AM signal is then amplified by amplifier U47 and applied to wire loop **22** by way of coupling capacitor **461** and resistor **462**. Being alerted to the breakage of wire loop **22** by the signals provided by audio transducer **483** and LED **484**, a user may then use a conventional AM radio to accurately locate the site of the break in wire loop **22**. This can be done by carrying an AM radio along the path of wire loop **22** and identifying the site at which distinctive 16 Hz pulses are heard at a maximum audio volume.

[0134] A parts listing for the circuitry of the wire loop unit **21** of **FIG. 11A** and **FIG. 11B** is set forth below in Table 3.

[0135] Having described the structure and operation of wire loop unit 21 in detail, it is now appropriate to discuss the operation of receiver/stimulator 14 in further detail including the manner in which the microprocessor 281 of control and stimulation subsystem 130 operates.

[0136] Referring to FIG. 13, there is illustrated a Main Routine which is commenced by microprocessor 281, as indicated at block 500, immediately upon application of operating power to receiver/stimulator unit 14 by installing battery 138. As indicated at block 502, microprocessor 281 determines the status of switch 310 by reading the logic level status of ports RB6 and RB7 as described earlier and selecting an appropriate stimulation routine to be executed when microprocessor 281 determines that one or more programmed preconditions associated with the reception of an RF signal 18 have been satisfied. Such preconditions include, but are not necessarily limited to, an indication that receiver/stimulator unit 14 has received an RF signal 18 identified by a 16 bit (four digit hexadecimal) code which that particular receiver/stimulator unit 14 has been programmed to respond to by administering an aversive stimulus to animal 12. According to the status of ports RB6 and RB7, microprocessor 281 selects a stimulation routine for delivering either an audible tone only, an audible tone combined with a high intensity ("High") electrical shock or an audible tone combined with a lower intensity ("Low") electrical shock. Within a given stimulation routine, various stimulation parameters can be programmed to be selected based on which particular digital code receiver/stimulator unit 14 detects at a given time. Such parameters include the duration of audio tone bursts and the lengths of time intervals between successive bursts. Similarly, the repetition rate of shock pulses 341, the number of shock pulses 341 and/or the length of delay intervals between successive series of shock pulses 341 can all be determined on a preprogrammed basis according to which particular digital code is received by a particular receiver/stimulator unit 14 at any given time.

[0137] Once the appropriate stimulation routine is selected, microprocessor 241 initializes a counter referred to by the mnemonic "MOTION" to an initial numerical value as indicated at block 504. The purpose of doing so will become apparent upon explanation of the Motion Check

subroutine of FIG. 15. As block 506 indicates, microprocessor 281 then checks for a low battery condition and causes LED 308 to blink if battery 138 is determined to be low. This is accomplished simply by reading input port RB4 at pin 10 of microprocessor 281 and generating an intermittent output signal at output port RA2 in the event the status of port RB4 indicates that low voltage detector 307 detects a voltage of less than 2.35 volts at power supply rail 283. The stored operating program then causes microprocessor 281 to successively call a Motion Check subroutine as indicated at block 508 and a Detect subroutine as indicated at block 510. Program flow then loops back to block 506 as indicated to repetitively perform the battery check and the subroutines Motion Check and Detect so long as operating power continues to be available to receiver/stimulator unit 14. The Motion Check subroutine will now be described with reference to FIG. 14.

[0138] The Motion Check subroutine serves to conserve battery 138 by selectively terminating the flow of operating power to portions of receiver/stimulator unit 14 during periods when animal 12 or 12' is determined not to be moving. As indicated at block 520, the Motion Check subroutine starts immediately upon being called by the Main routine of FIG. 13. As indicated at block 522, the status of motion switch 299 is checked by reading the status of input port RB5 and storing this status in a register designated by the variable name "Mx." As block 524 indicates, microprocessor 281 then compares the present status of register Mx to the value, Mx-1, stored during the immediately preceding execution of the Motion Check subroutine. If the two values differ, it is assumed that animal 12 is in motion. As blocks 526 and 528 show, the value of register MOTION is then checked and, provided this value does not exceed its predetermined maximum value of two-hundred fifty-five (255), the MOTION register is incremented. If the comparison of block 524 indicates the status of motion switch 299 has not changed, animal 12 is assumed not to be in motion. As blocks 530 and 532 indicate, the value of the MOTION register is then checked and decremented unless it already equals zero. After having been checked and, if necessary, incremented or decremented as a result of the execution of blocks 526 and/or 528 or blocks 530 and/or 532, the status of the MOTION register is again checked and compared

with a predetermined numerical value such as twenty as indicated at block **534**. In the event the present value stored in the MOTION register exceeds twenty, animal **12** is determined to be sufficiently active to warrant monitoring. In that event, a logical "0" value is written to port RA2 as indicated at block **536**, thereby causing FET **140** to either continue conducting or begin conducting the flow of current from battery **138** to those portions of receiver **133** which consume significant amounts of power. In the event FET **140** was previously non-conducting, a twenty millisecond delay loop is executed to allow receiver **133** to stabilize before attempting to detect any encroachment of boundary **20** and/or **23**. After block **536** is executed, the Motion Check subroutine ends as indicated at block **538** and program flow resumes with the Main Routine of **FIG. 13**. On the other hand, if the comparison performed at block **534** indicates the present value of the MOTION register does not exceed the predetermined threshold value of twenty, it is assumed that animal **12** has been sufficiently inactive as to warrant conserving power. In that event, as indicated at block **538**, FET **140** is turned "off" by writing a logical "1" value to port RA2. A one hundred fifty millisecond delay loop is then entered and the Motion Check subroutine is again called in order to determine whether it is yet appropriate to turn FET **140**"on" and commence monitoring for an encroachment of a boundary **20** and/or wire loop boundary **20** due to an apparent resumption of movement on the part of animal **12**. If and when animal **12** resumes movement, FET **140** will once again be turned on when block **536** is next executed. Upon ending the Motion Check subroutine at block **538**, the Main Routine of **FIG. 13** resumes at block **510** by calling the Detect Subroutine which will now be described with reference to **FIG. 15**.

[0139] **FIG. 15** summarizes the Detect subroutine which is executed by microprocessor **281** to determine whether certain preconditions associated with reception of an RF signal **18** have been satisfied and if so, to initiate administration of an appropriate form of aversive stimulation. Two such preconditions are imposed to reduce the possibility that the animal **12** will receive aversive stimulation even though it has not encroached upon any boundary **20** or **23**. The first precondition which must be satisfied before microprocessor **281** will initiate any form of aversive stimulation is reception of an RF signal **18** bearing a sixteen bit (four digit hexadecimal) code to which the particular receiver/stimulator unit **14** has been programmed to respond. As noted previously, each receiver/stimulator unit may be programmed to respond to more than one such code according to preprogrammed Boolean criteria.

[0140] In order to determine whether and when such a first precondition is satisfied, the Detect subroutine starts as indicated at block **560** and proceeds immediately as indicated at block **562** to initialize two separate 16 bit (four digit hexadecimal) registers by loading each with data such as "AAAA" which does not correspond to any valid code receiver/stimulator unit **14** is to respond to but is otherwise arbitrary. These registers are referred to as "rolling" registers because they are continually updated with new data one bit at a time on a first-in, first-out (FIFO) basis. One of these rolling registers continually reflects the code data signal **275** presented to the input port RB2 at pin **8** of microprocessor **281** while the other continually reflects the quadrature code data signal presented to the input port RB3 at pin **9** of microprocessor **281**. This is achieved as indicated at block

564 by reading the states of input ports RB2 and RB3 at least once during each 1.953 millisecond interval depicted in **FIG. 3**, determining the value of the data during that interval and storing that data in a respective one of each of the rolling registers. Each rolling register is updated in this manner once every 1.953 milliseconds on a FIFO basis.

[0141] As block **566** indicates, microprocessor **281** next determines whether the data presently appearing in either of the two rolling registers satisfies a Boolean test and thus constitutes a "valid" code associated with any of the transmitters **17** whose RF signals **18** bear a code to which the particular receiver/stimulator unit **14** is programmed to respond. If only one such valid code has been preprogrammed, the data in each of the two rolling registers is compared with that one code. If a plurality of such codes have been programmed, microprocessor **281** compares each one with the data in each of the two rolling registers and determines whether a Boolean test defining one or some logical combination of the preprogrammed codes is satisfied by the data in either of the two rolling registers. If such a Boolean test is satisfied, microprocessor **281** determines that a valid code from a transmitter **17** has been received. If no valid code associated with any of the transmitters **17** is detected, it is assumed no applicable boundary **20** has been encroached upon.

[0142] In such event, microprocessor **281** proceeds as indicated at block **568** to determine whether the data in either of the two rolling registers constitutes a valid code associated with a wire loop unit **21**. Except that the preprogrammed codes and/or the Boolean criteria applied may be different, the execution of block **568** is otherwise the same as block **566** as just described. If no valid code associated with a wire loop unit **21** is detected, it is assumed no applicable wire loop boundary **23** has been encroached upon. In such event, program flow continually loops back to block **564** unless and until a valid code is detected upon a subsequent execution of block **566** and/or block **568**. If desired, the number of times the loop consisting of blocks **564**, **566** and **563** can optionally be counted by a software counter. By comparing the present value of the counter to a predetermined upper limit and redirecting program flow to end the Detect subroutine when that upper limit is reached, it can be assured that the battery check of block **506** will be performed no less frequently than may be appropriate to detect a low battery condition before battery **138** becomes unable to operate receiver/stimulator unit **14** reliably.

[0143] In the event microprocessor **281** determines as a result of the execution of block **566** and/or block **568** that a valid code has been received from a transmitter **17** and/or wire loop **22**, a first precondition to the administration of an aversive stimulus is deemed satisfied. However, microprocessor **281** preferably does not immediately initiate administration of any stimulus. Rather, microprocessor **281** proceeds to determine whether a second necessary precondition is also satisfied. According to this aspect of the invention, no stimulus will be administered unless a subsequent transmission bearing the same code as a previous transmission is received during a limited window of time whose width and spacing in time with respect to a prior transmission are consistent with the duration and repetition rate known to be associated with transmissions emanating from a particular source. As the timing diagram of **FIG. 3** reflects, the hexadecimal code identifying a transmitter **17** repeats regu-

larly beginning 93.75 mSec after its immediately preceding transmission has been completed. Likewise, as explained above, the code associated with a wire loop unit **21** repeats regularly beginning 31.25 mSec after its immediately preceding transmission has been completed. By requiring a similarly encoded transmission to be received during a limited window of time consistent with one or the other of these known sets of timing parameters, the likelihood of stimulating an animal **12** when no boundary **20** or **23** has actually been encroached upon is greatly diminished.

[0144] In the preferred embodiment, this is achieved as shown in **FIG. 15** by promptly re-initializing both of the rolling registers as indicated at block **570** as soon as a valid code associated with a transmitter **17** is detected. A 93.75 millisecond delay is then executed as indicated at block **572**. As soon as the delay of block **572** is completed, input ports RB2 and RB3 of microprocessor **281** are read and the data so acquired is stored in each respective rolling register in the manner explained above as indicated at block **574**. Once sixteen bits of data have been read and stored in each of the rolling registers in this manner, microprocessor **281** compares the data in each of the two rolling registers with the valid code data detected at block **566**. If the code matches the data in either of the two rolling registers, a second predetermined condition is deemed satisfied whereupon both rolling registers are promptly re-initialized as indicated at block **576** prior to initiating stimulation. If the code does not match the data in either of the two rolling registers, the second predetermined condition is not satisfied and no stimulation is initiated. Instead, the Detect subroutine ends as indicated at block **592** and program flow is redirected to block **506** of the Main routine of **FIG. 13**.

[0145] As block **578** indicates, microprocessor **281** next selects a stimulation routine corresponding to the particular code determined to have been received at blocks **566** and **574**. In so doing, microprocessor **281** selects at least one stimulation parameter in accordance with the particular digital code received. As **FIG. 10** reflects, the stimulation parameters so selected may include the duration of stimulation, the repetition rate of stimulation, the number of times stimulation is applied in response to a single encroachment and/or the duration of intervals separating successive stimuli. Microprocessor **281** then executes the selected stimulation routine by driving port RA1 or port RA1 and port RA0 to generate the form and intensity of stimulation selected according to the status of switch **310** as determined at block **502** of the Main Routine of **FIG. 13**. As block **578** indicates, stimulation is administered for an interval of 93.75 milliseconds after which program flow is promptly redirected to block **574** is indicated. Stimulation continues to be applied in the manner determined by the selected stimulation routine until a valid code is no longer detected at block **574**. In that event, the Detect subroutine ends as indicated at block **580**.

[0146] Microprocessor **281** operates in a similar manner to determine whether a second predetermined condition associated with reception of an RF signal **18** from wire loop **22** is satisfied. As block **582** of **FIG. 15** reflects, both rolling registers are promptly re-initialized as soon as a valid code associated with wire loop unit **21** is detected at block **568**. Consistent with the 31.25 millisecond time interval between the end of one transmission of the code associated with wire loop unit **21** and the beginning of the next, a 31.25 milli-

second delay is executed as indicated at block **584**. As soon as that delay is completed, input ports RB2 and RB3 of microprocessor **281** are read and the data so acquired is stored in each respective rolling register as indicated at block **586**. Once sixteen bits of data have been read and stored in each of the rolling registers in this manner, microprocessor **281** compares the data in each of the two rolling registers with the valid wire loop code detected at block **568**. If that code matches the data present in either of the two rolling registers, the second predetermined condition is deemed satisfied. In that event, both rolling registers are re-initialized as indicated at block **588**. If there is no match, however, the second predetermined condition is not satisfied. Rather than initiating stimulation, the Detect subroutine ends as block **592** indicates and program flow is redirected to block **506** of the Main routine of **FIG. 13**.

[0147] As block **590** reflects, microprocessor **281** then selects a stimulation routine corresponding to the particular code determined to have been received at blocks **568** and **586** and thereby selects one or more stimulation parameters such as those identified above. Microprocessor **281** then executes the selected stimulation routine by driving port RA1 or port RA1 and port RA0 to generate the form and intensity of stimulation selected according to the status of selector switch **310** as determined at block **502** of the Main routine of **FIG. 13**. As block **590** indicates, stimulation is administered for an interval of 31.25 milliseconds after which program flow is promptly redirected to block **586** as indicated. Stimulation continues to be applied in the manner determined by the selected stimulation routine until a valid code is no longer detected at block **586**. In that event, the Detect subroutine ends as indicated at block **592**. Preferred stimulation routines are illustrated in **FIG. 10**. As noted previously, microprocessor **281** is preferably programmed to include a software timer, loop counter or other facility to limit the maximum number of times and/or the maximum duration of stimulation delivered as the result of any single boundary encroachment episode or series of episodes occurring closely in time to one another.

[0148] While the foregoing constitute preferred embodiments of the present invention, it is to be understood that the invention is not limited thereto and that in light of the present disclosure, various alternative embodiments will be apparent to persons skilled in the art. Accordingly, it is to be recognized that changes can be made without departing from the scope of the invention as particularly pointed out and distinctly claimed in the appended claims which shall be construed to encompass all legal equivalents thereof.

What is claimed is:

1. A radio frequency (RF) signaling system, comprising:

(a) a battery;

(b) a resonant circuit coupled to said battery, said resonant circuit being resonant substantially at an RF carrier frequency, said resonant circuit including an antenna and deriving operating energy only from said battery; and

(c) a drive circuit coupled to said battery and said resonant circuit, said drive circuit deriving operating energy only from said battery and delivering to said resonant circuit, at substantially said RF carrier frequency, brief pulses of electrical energy separated by intervals of

time in order to cause said resonant circuit to resonate, thereby exciting said antenna to transmit an RF signal at substantially said RF carrier frequency.

2. The system of claim 1 wherein said drive circuit comprises a circuit which delivers said pulses of electrical energy at a duty cycle of less than about one percent (1%).

3. The system of claim 1 wherein said drive circuit comprises a circuit which delivers said pulses of electrical energy at a duty cycle of less than about five percent (5%).

4. The system of claim 1 wherein said drive circuit comprises a circuit which delivers said pulses of electrical energy at a duty cycle of less than about fifteen percent (15%).

5. The system of claim 1 wherein said antenna is electrically small and said RF carrier frequency is a frequency of about ten kilohertz or less.

6. The system of claim 1 wherein said RF signal comprises a signal having a magnetic field whose magnitude decreases substantially in proportion to the cube of increasing distance from said antenna.

7. The system of claim 1 wherein said apparatus further comprises circuitry for controlling the phase of said pulses to digitally encode said RF signal.

8. The system of claim 1 wherein said RF signal comprises a signal having an amplitude bounded by an envelope having a substantially constant magnitude.

9. The system of claim 1 further comprising an isolation circuit operably interposed between said drive circuit and said resonant circuit, said isolation circuit, said isolation circuit effectively electrically isolating said drive circuit from said resonant circuit during at least a portion of said intervals whereby loading effects of said drive circuit on said resonant circuit are reduced, efficiency of said transmitter increased and useful life of said battery prolonged.

10. A system for controlling the whereabouts of an animal, said system comprising:

(a) a battery;

(b) a transmitter coupled to said battery said transmitter transmitting at predetermined intervals radio frequency (RF) signals defining a boundary for the animal said

transmitter deriving all energy required for operating said transmitter only from said battery;

(c) a receiver from receiving said signals; and

(d) a stimulator operably coupled to said receiver for administering at least one stimulus to the animal to deter the animal from encroachment of said boundary in response to determining, based on said RF signals, whether at least one predetermined condition indicating encroachment of said boundary has been satisfied.

11. The system of claim 10 wherein said predetermined condition comprises reception of at least one of said RF signals during a predetermined window of time.

12. The system of claim 11 wherein said window of time is a window of time occurring subsequent to reception of a previously transmitted one of said RF signals.

13. The system of claim 10 wherein said transmitter includes:

(a) a resonant circuit which includes a resonant circuit resonant substantially at an RF carrier frequency, said resonant circuit including an antenna, and;

(b) a drive circuit which delivers to said resonant circuit at substantially said RF carrier frequency, pulses of electrical energy separated by intervals of time so as to cause said antenna to intermittently transmit said RF signal at substantially said RF carrier frequency.

14. The system of claim 12 further comprising an isolation circuit operably interposed between said drive circuit and said resonant circuit, said isolation circuit effectively electrically isolating said drive circuit from said resonant circuit during at least a portion of said intervals whereby loading effects of said drive circuit on said resonant circuit are reduced efficiency of said transmitter increased and useful life of said battery prolonged.

15. The system of claim 10 wherein said RF signal comprises a signal having an amplitude bounded by an envelope of substantially constant magnitude.
