(54) Title: A METHOD OF CONTROLLING INITIAL POWER RAMP-UP IN CDMA SYSTEMS BY USING SHORT CODES

(57) Abstract

A system and method of controlling transmission power during the establishment of a channel in a CDMA communication system utilize the transmission of a short code from a subscriber unit to a base station during initial power ramp-up. The short code is a sequence for detection by the base station which has a much shorter period than a conventional spreading code. The ramp-up starts from a power level that is guaranteed to be lower than the required power level for detection by the base station. The subscriber unit quickly increases transmission power while repeatedly transmitting the short code until the signal is detected by the base station. Once the base station detects the short code, it sends an indication to the subscriber unit to cease increasing transmission power. The use of short codes limits power overshoot and interference to other subscriber stations and permits the base station to quickly synchronize to the spreading code used by the subscriber unit.

**A METHOD OF CONTROLLING INITIAL POWER RAMP-UP
IN CDMA SYSTEMS BY USING SHORT CODES**

BACKGROUND OF THE INVENTION

5 **Field of the Invention**

The present invention relates generally to CDMA communication systems. More specifically, the present invention relates to a CDMA communication system which utilizes the transmission of short codes from subscriber units to a base station to reduce the time required for the base station to detect the signal from a subscriber unit. The improved detection time allows a faster ramp-up of the initial transmit power from the subscriber units while reducing the unnecessary power overshoot.

15

Description of Related Art

The use of wireless telecommunication systems has grown dramatically in the last decade as the reliability and capacity of the systems have improved. Wireless communication systems are being utilized in a variety of applications where land line based systems are impractical or impossible to use. Applications of wireless communications include cellular phone communications, communications in remote locations, and temporary communications for disaster recovery. Wireless communication systems have also become an economically viable alternative to replacing aging telephone lines and outdated telephone equipment.

25

30

The portion of the RF spectrum available for use by wireless communication systems is a critical resource. The RF spectrum must be shared among all commercial, governmental

-2-

and military applications. There is a constant desire to improve the efficiency of wireless communication systems in order to increase system capacity.

Code division multiple access (CDMA) wireless
5 communication systems have shown particular promise in this area. Although more traditional time division multiple access (TDMA) and frequency division multiple access (FDMA) systems have improved using the latest technological advances, CDMA systems, in particular Broadband Code Division Multiple
10 Access™ (B-CDMA™) systems, have significant advantages over TDMA and FDMA systems. This efficiency is due to the improved coding and modulation density, interference rejection and multipath tolerance of B-CDMA™ systems, as well as reuse of the same spectrum in every communication cell. The format of
15 CDMA communication signals also makes it extremely difficult to intercept calls, thereby ensuring greater privacy for callers and providing greater immunity against fraud.

In a CDMA system, the same portion of the frequency spectrum is used for communication by all subscriber units.
20 Each subscriber unit's baseband data signal is multiplied by a code sequence, called the "spreading code", which has a much higher rate than the data. The ratio of the spreading code rate to the data symbol rate is called the "spreading factor" or the "processing gain". This coding results in a much wider
25 transmission spectrum than the spectrum of the baseband data signal, hence the technique is called "spread spectrum". Subscriber units and their communications can be discriminated by assigning a unique spreading code to each communication

-3-

link which is called a CDMA channel. Since all communications are sent over the same frequency band, each CDMA communication overlaps communications from other subscriber units and noise-related signals in both frequency and time.

5 The use of the same frequency spectrum by a plurality of subscriber units increases the efficiency of the system. However, it also causes a gradual degradation of the performance of the system as the number of users increase. Each subscriber unit detects communication signals with its
10 unique spreading code as valid signals and all other signals are viewed as noise. The stronger the signal from a subscriber unit arrives at the base station, the more interference the base station experiences when receiving and demodulating signals from other subscriber units. Ultimately,
15 the power from one subscriber unit may be great enough to terminate communications of other subscriber units. Accordingly, it is extremely important in wireless CDMA communication systems to control the transmission power of all subscriber units. This is best accomplished by using a closed
20 loop power control algorithm once a communication link is established.

The control of transmission power is particularly critical when a subscriber unit is attempting to initiate communications with a base station and a power control loop
25 has not yet been established. Typically, the transmission power required from a subscriber unit changes continuously as a function of the propagation loss, interference from other subscribers, channel noise, fading and other channel

-4-

characteristics. Therefore, a subscriber unit does not know the power level at which it should start transmitting. If the subscriber unit begins transmitting at a power level that is too high, it may interfere with the communications of other subscriber units and may even terminate the communications of other subscriber units. If the initial transmission power level is too low, the subscriber unit will not be detected by the base station and a communication link will not be established.

There are many methods for controlling transmission power in a CDMA communication system. For example, U.S. Patent No. 5,056,109 (Gilhousen et al.) discloses a transmission power control system wherein the transmission power of the subscriber unit is based upon periodic signal measurements from both the subscriber unit and the base station. The base station transmits a pilot signal to all subscriber units which analyze the received pilot signal, estimate the power loss in the transmitted signal and adjust their transmission power accordingly. Each subscriber unit includes a non-linear loss output filter which prevents sudden increases in power which would cause interference to other subscriber units. This method is too complex to permit a base station to quickly acquire a subscriber unit while limiting the interference to other subscriber units. In addition, the propagation losses, interference and noise levels experienced in a forward link (transmission from the base station to a subscriber unit) is often not the same as in a reverse link (transmission from a

-5-

subscriber unit to the base station). Reverse link power estimates based on forward link losses are not precise.

Many other types of prior art transmission power control systems require complex control signaling between communicating units or preselected transmission values to control transmission power. These power control techniques are inflexible and often impractical to implement.

Additionally, EP 0 565 507 A2 discloses a system for minimizing interference between two radio stations at the initiation of radio communications. A mobile station initiates a low level access signal and incrementally increases the transmission power level until the base station detects the signal. Once detected, the power level of the message is maintained at the detected level so that the signal interference is avoided. EP 0 565 507 A2 also discloses a method for synchronizing random access communications between mobile stations and the base station despite the variations in the distance between them.

Accordingly, there is a need for an efficient method of controlling the initial ramp-up of transmission power by subscriber units in a wireless CDMA communication system.

SUMMARY OF THE INVENTION

The present invention comprises a novel method of controlling transmission power during the establishment of a channel in a CDMA communication system by utilizing the transmission of a short code from a subscriber unit to a base station during initial power ramp-up. The short code is a

-5a-

sequence for detection by the base station which has a much shorter period than a conventional spreading code. The ramp-up starts from a power level that is guaranteed to be lower than the required power level for detection by the base station. The subscriber unit quickly increases transmission power while repeatedly transmitting the short code until the signal is detected by the base station. Once the base station detects the short code, it sends an indication to the subscriber unit to cease increasing transmission power. The use of short codes limits power overshoot and interference to other subscriber stations and permits the base station to

AMENDED SHEET

-6-

quickly synchronize to the spreading code used by the subscriber unit.

Accordingly, the invention herein comprises a network for communicating between a base station and at least one subscriber unit, both said base station and subscriber unit having means for transmitting and detecting signals, including a system for reducing the reacquisition time of said subscriber unit by said base station, the system comprising the base station including means for detecting an access signal from said subscriber unit at a sufficient power level and proper delay; means for generating a confirmation signal for transmission to said subscriber unit in response to said access signal; and the subscriber unit including means for generating said access signal for transmission to said base station; means for varying the transmission power and changing the delay of said transmitted access signal; means for detecting said confirmation signal; and means for ceasing the variation in said transmission power and the change in delay when said confirmation signal is received; wherein said proper delay is a round trip delay associate with a subscriber unit at a fixed distance from said base station.

The invention herein further comprises a method for reducing the reacquisition time of a subscriber unit by a base station in a network for communicating between a base station and at least one subscriber unit; the method comprising transmitting an access signal from a subscriber

-6a-

unit at a predetermined power transmission level and phase
delay; varying said transmission power and delay of said
access signal until a confirmation signal is received from
said base station; detecting said access signal at said base
5 station when a sufficient power level and proper delay have
been achieved; transmitting a confirmation signal from said
base station when said access signal has been detected;
receiving said confirmation signal at said subscriber unit;
and ceasing the variation in transmission power and delay
10 from said subscriber unit when said confirmation signal is
received; wherein said proper delay is a round trip delay
associated with a subscriber unit at a fixed distance from
the base station.

Accordingly, it is an object of the present invention to
15 provide an improved technique for controlling power ramp-up
during establishment of a communication channel between a
CDMA subscriber unit and base station.

Other objects and advantages of the present invention
will become apparent after reading the description of a
20 presently preferred embodiment.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

15 The preferred embodiment will be described with reference to the drawing figures where identical numerals represent similar elements throughout.

20 A communication network 10 embodying the present invention is shown in **Figure 1**. The communication network 10 generally comprises one or more base stations 14, each of which is in wireless communication with a plurality of subscriber units 16, which may be fixed or mobile. Each subscriber unit 16 communicates with either the closest base station 14 or the base station 14 which provides the strongest
25 communication signal. The base stations 14 also communicate with a base station controller 20, which coordinates communications among base stations 14. The communication network 10 may also be connected to a public switched

-9-

telephone network (PSTN) 22, wherein the base station controller 20 also coordinates communications between the base stations 14 and the PSTN 22. Preferably, each base station 14 communicates with the base station controller 20 over a wireless link, although a land line may also be provided. A land line is particularly applicable when a base station 14 is in close proximity to the base station controller 20.

The base station controller 20 performs several functions. Primarily, the base station controller 20 provides all of the operations, administrative and maintenance (OA&M) signaling associated with establishing and maintaining all of the wireless communications between the subscriber units 16, the base stations 14, and the base station controller 20. The base station controller 20 also provides an interface between the wireless communication system 10 and the PSTN 22. This interface includes multiplexing and demultiplexing of the communication signals that enter and leave the system 10 via the base station controller 20. Although the wireless communication system 10 is shown employing antennas to transmit RF signals, one skilled in the art should recognize that communications may be accomplished via microwave or satellite uplinks. Additionally, the functions of the base station controller 20 may be combined with a base station 14 to form a "master base station".

Referring to **Figure 2**, the propagation of signals between a base station 14 and a plurality of subscriber units 16 is shown. A two-way communication channel (link) 18 comprises a signal transmitted 20 (Tx) from the base station 14 to the

-10-

subscriber unit 16 and a signal received 22 (Rx) by the base station 14 from the subscriber unit 16. The Tx signal 20 is transmitted from the base station 14 and is received by the subscriber unit 16 after a propagation delay Δt . Similarly, the Rx 22 signal originates at the subscriber unit 16 and terminates at the base station 14 after a further propagation delay Δt . Accordingly, the round trip propagation delay is $2\Delta t$. In the preferred embodiment, the base station 14 has an operating range of approximately 30 kilometers. The round trip propagation delay 24 associated with a subscriber unit 16 at the maximum operating range is 200 microseconds.

It should be apparent to those of skill in the art that the establishment of a communication channel between a base station and a subscriber unit is a complex procedure involving many tasks performed by the base station 14 and the subscriber unit 16 which are outside the scope of the present invention. The present invention is directed to initial power ramp-up and synchronization during the establishment of a communication channel.

Referring to **Figure 3**, the signaling between a base station 14 and a subscriber unit 16 is shown. In accordance with the present invention, the base station 14 continuously transmits a pilot code 40 to all of the subscriber units 16 located within the transmitting range of the base station 14. The pilot code 40 is a spreading code which carries no data bits. The pilot code 40 is used for subscriber unit 16 acquisition and synchronization, as well as for determining

-11-

the parameters of the adaptive matched filter used in the receiver.

The subscriber unit 16 must acquire the pilot code 40 transmitted by the base station 14 before it can receive or transmit any data. Acquisition is the process whereby the subscriber unit 16 aligns its locally generated spreading code with the received pilot code 40. The subscriber unit 16 searches through all of the possible phases of the received pilot code 40 until it detects the correct phase, (the beginning of the pilot code 40).

The subscriber unit 16 then synchronizes its transmit spreading code to the received pilot code 40 by aligning the beginning of its transmit spreading code to the beginning of the pilot code 40. One implication of this receive and transmit synchronization is that the subscriber unit 16 introduces no additional delay as far as the phase of the spreading codes are concerned. Accordingly, as shown in Figure 3, the relative delay between the pilot code 40 transmitted from the base station 14 and the subscriber unit's transmit spreading code 42 received at the base station 14 is $2\Delta t$, which is solely due to the round trip propagation delay.

In the preferred embodiment, the pilot code is 29,877,120 chips in length and takes approximately 2 to 5 seconds to transmit, depending on the spreading factor. The length of the pilot code 40 was chosen to be a multiple of the data symbol no matter what kind of data rate or bandwidth is used. As is well known by those of skill in the art, a longer pilot code 40 has better randomness properties and the frequency

-12-

response of the pilot code 40 is more uniform. Additionally, a longer pilot code 40 provides low channel cross correlation, thus increasing the capacity of the system 10 to support more subscriber units 16 with less interference. The use of a long pilot code 40 also supports a greater number of random short codes. For synchronization purposes, the pilot code 40 is chosen to have the same period as all of the other spreading codes used by the system 10. Thus, once a subscriber unit 16 acquires the pilot code 40, it is synchronized to all other signals transmitted from the base station 14.

During idle periods, when a call is not in progress or pending, the subscriber unit 16 remains synchronized to the base station 14 by periodically reacquiring the pilot code 40. This is necessary for the subscriber unit 16 to receive and demodulate any downlink transmissions, in particular paging messages which indicate incoming calls.

When a communication link is desired, the base station 14 must acquire the signal transmitted from the subscriber unit 16 before it can demodulate the data. The subscriber unit 16 must transmit an uplink signal for acquisition by the base station 14 to begin establishing the two-way communication link. A critical parameter in this procedure is the transmission power level of the subscriber unit 16. A transmission power level that is too high can impair communications in the whole service area, whereas a transmission power level that is too low can prevent the base station 14 from detecting the uplink signal.

-13-

In a first embodiment of the present invention the subscriber unit 16 starts transmitting at a power level guaranteed to be lower than what is required and increases transmission power output until the correct power level is achieved. This avoids sudden introduction of a strong interference, hence improving system 10 capacity.

The establishment of a communication channel in accordance with the present invention and the tasks performed by the base station 14 and a subscriber unit 16 are shown in **Figure 4**. Although many subscriber units 16 may be located within the operating range of the base station 14, reference will be made hereinafter to a single subscriber unit 16 for simplicity in explaining the operation of the present invention.

The base station 14 begins by continuously transmitting a periodic pilot code 40 to all subscriber units 16 located within the operating range of the base station 14 (**step 100**). As the base station 14 transmits the pilot code 40 (**step 100**), the base station 14 searches (**step 101**) for an "access code" 42 transmitted by a subscriber unit 16. The access code 42 is a known spreading code transmitted from a subscriber unit 16 to the base station 14 during initiation of communications and power ramp-up. The base station 14 must search through all possible phases (time shifts) of the access code 42 transmitted from the subscriber unit 16 in order to find the correct phase. This is called the "acquisition" or the "detection" process (**step 101**). The longer the access code

-14-

42, the longer it takes for the base station 14 to search through the phases and acquire the correct phase.

As previously explained, the relative delay between signals transmitted from the base station 14 and return signals received at the base station 14 corresponds to the round trip propagation delay $2\Delta t$. The maximum delay occurs at the maximum operating range of the base station 14, known as the cell boundary. Accordingly, the base station 14 must search up to as many code phases as there are in the maximum round trip propagation delay, which is typically less code phases than there are in a code period.

For a data rate R_b and spreading code rate R_c , the ratio $L = R_c/R_b$ is called the spreading factor or the processing gain. In the preferred embodiment of the present invention, the cell boundary radius is 30 km, which corresponds to approximately between 1000 and 2500 code phases in the maximum round trip delay, depending on the processing gain.

If the base station 14 has not detected the access code after searching through the code phases corresponding to the maximum round trip delay the search is repeated starting from the phase of the pilot code 40 which corresponds to zero delay (step 102).

During idle periods, the pilot code 40 from the base station 14 is received at the subscriber unit 16 which periodically synchronizes its transmit spreading code generator thereto (step 103). If synchronization with the pilot code 40 is lost, the subscriber unit 16 reacquires the pilot code 40 and resynchronizes (step 104).

-15-

When it is desired to initiate a communication link, the subscriber unit 16 starts transmitting the access code 42 back to the base station 14 (step 106). The subscriber unit 16 continuously increases the transmission power while retransmitting the access code 42 (step 108) until it receives an acknowledgment from the base station 14. The base station 14 detects the access code 42 at the correct phase once the minimum power level for reception has been achieved (step 110). The base station 14 subsequently transmits an access code detection acknowledgment signal (step 112) to the subscriber unit 16. Upon receiving the acknowledgment, the subscriber unit ceases the transmission power increase (step 114). With the power ramp-up completed, closed loop power control and call setup signaling is performed (step 116) to establish the two-way communication link.

Although this embodiment limits subscriber unit 16 transmission power, acquisition of the subscriber unit 16 by the base station 14 in this manner may lead to unnecessary power overshoot from the subscriber unit 16, thereby reducing the performance of the system 10.

The transmission power output profile of the subscriber unit 16 is shown in Figure 5. At t_0 , the subscriber unit 16 starts transmitting at the starting transmission power level P_0 , which is a power level guaranteed to be less than the power level required for detection by the base station 14. The subscriber unit 16 continually increases the transmission power level until it receives the detection indication from the base station 14. For the base station 14 to properly

-16-

detect the access code 42 from the subscriber unit 16 the access code 42 must: 1) be received at a sufficient power level; and 2) be detected at the proper phase. Accordingly, referring to **Figure 5**, although the access code 42 is at a sufficient power level for detection by the base station 14 at t_p , the base station 14 must continue searching for the correct phase of the access code 42 which occurs at t_A .

Since the subscriber unit 16 continues to increase the output transmission power level until it receives the detection indication from the base station 14, the transmission power of the access code 42 exceeds the power level required for detection by the base station 14. This causes unnecessary interference to all other subscriber units 16. If the power overshoot is too large, the interference to other subscriber units 16 may be so severe as to terminate ongoing communications of other subscriber units 16.

The rate that the subscriber unit 16 increases transmission power to avoid overshoot may be reduced, however, this results in a longer call setup time. Those of skill in the art would appreciate that adaptive ramp-up rates can also be used, yet these rates have shortcomings and will not appreciably eliminate power overshoot in all situations.

The preferred embodiment of the present invention utilizes "short codes" and a two-stage communication link establishment procedure to achieve fast power ramp-up without large power overshoots. The spreading code transmitted by the subscriber unit 16 is much shorter than the rest of the spreading codes (hence the term short code), so that the

-17-

number of phases is limited and the base station 14 can quickly search through the code. The short code used for this purpose carries no data.

The tasks performed by the base station 14 and the subscriber unit 16 to establish a communication channel using short codes in accordance with the preferred embodiment of the present invention are shown in **Figures 6A** and **6B**. During idle periods, the base station 14 periodically and continuously transmits the pilot code to all subscriber units 16 located within the operating range of the base station 14 (**step 150**). The base station 14 also continuously searches for a short code transmitted by the subscriber unit 16 (**step 152**). The subscriber unit 16 acquires the pilot code and synchronizes its transmit spreading code generator to the pilot code. The subscriber unit 16 also periodically checks to ensure it is synchronized. If synchronization is lost, the subscriber unit 16 reacquires the pilot signal transmitted by the base station (**step 156**).

When a communication link is desired, the subscriber unit 16 starts transmitting a short code at the minimum power level P_0 (**step 158**) and continuously increases the transmission power level while retransmitting the short code (**step 160**) until it receives an acknowledgment from the base station 14 that the short code has been detected by the base station 14.

The access code in the preferred embodiment, as previously described herein, is approximately 30 million chips in length. However, the short code is much smaller. The short code can be chosen to be any length that is sufficiently

-18-

short to permit quick detection. There is an advantage in choosing a short code length such that it divides the access code period evenly. For the access code described herein, the short code is preferably chosen to be 32, 64 or 128 chips in length. Alternatively, the short code may be as short as one symbol length, as will be described in detail hereinafter.

Since the start of the short code and the start of the access code are synchronized, once the base station 14 acquires the short code, the base station 14 knows that the corresponding phase of the access code is an integer multiple of N chips from the phase of the short code where N is the length of the short code. Accordingly, the base station 14 does not have to search all possible phases corresponding to the maximum round trip propagation delay.

Using the short code, the correct phase for detection by the base station 14 occurs much more frequently. When the minimum power level for reception has been achieved, the short code is quickly detected (**step 162**) and the transmission power overshoot is limited. The transmission power ramp-up rate may be significantly increased without concern for a large power overshoot. In the preferred embodiment of the present invention, the power ramp-up rate using the short code is 1 dB per millisecond.

The base station 14 subsequently transmits a short code detection indication signal (**step 164**) to the subscriber unit 16 which enters the second stage of the power ramp-up upon receiving this indication. In this stage, the subscriber unit 16 ceases transmitting the short code (**step 166**) and starts

-19-

continuously transmitting a periodic access code (**step 166**). The subscriber unit 16 continues to ramp-up its transmission power while transmitting the access code, however the ramp-up rate is now much lower than the previous ramp-up rate used with the short code (**step 168**). The ramp-up rate with the access code is preferably 0.05 dB per millisecond. The slow ramp-up avoids losing synchronization with the base station 14 due to small changes in channel propagation characteristics.

At this point, the base station 14 has detected the short code at the proper phase and power level (**step 162**). The base station 14 must now synchronize to the access code which is the same length as all other spreading codes and much longer than the short code. Utilizing the short code, the base station 14 is able to detect the proper phase of the access code much more quickly. The base station 14 begins searching for the proper phase of the access code (**step 170**). However, since the start of the access code is synchronized with the start of the short code, the base station 14 is only required to search every N chips; where N = the length of the short code. In summary, the base station 14 quickly acquires the access code of the proper phase and power level by: 1) detecting the short code; and 2) determining the proper phase of the access code by searching every N chips of the access code from the beginning of the short code.

If the proper phase of the access code has not been detected after searching the number of phases in the maximum round trip delay the base station 14 restarts the search for

-20-

the access code by searching every chip instead of every N chips (**step 172**). When the proper phase of the access code has been detected (**step 174**) the base station 14 transmits an access code detection acknowledgment (**step 176**) to the subscriber unit 16 which ceases the transmission power increase (**step 178**) upon receiving this acknowledgment. With the power ramp-up completed, closed loop power control and call setup signaling is performed (**step 180**) to establish the two-way communication link.

Referring to **Figure 7**, although the starting power level P_0 is the same as in the prior embodiment, the subscriber unit 16 may ramp-up the transmission power level at a much higher rate by using a short code. The short code is quickly detected after the transmission power level surpasses the minimum detection level, thus minimizing the amount of transmission power overshoot.

Although the same short code may be reused by the subscriber unit 16, in the preferred embodiment of the present invention the short codes are dynamically selected and updated in accordance with the following procedure. Referring to **Figure 8**, the period of the short code is equal to one symbol length and the start of each period is aligned with a symbol boundary. The short codes are generated from a regular length spreading code. A symbol length portion from the beginning of the spreading code is stored and used as the short code for the next 3 milliseconds. Every 3 milliseconds, a new symbol length portion of the spreading code replaces the old short code. Since the spreading code period is an integer multiple

-21-

of 3 milliseconds, the same short codes are repeated once every period of the spreading code. Periodic updating of the short code averages the interference created by the short code over the entire spectrum.

5 A block diagram of the base station 14 is shown in **Figure 9**. Briefly described, the base station 14 comprises a receiver section 50, a transmitter section 52 and a diplexer 54. An RF receiver 56 receives and down-converts the RF signal received from the diplexer 54. The receive spreading code generator 58 outputs a spreading code to both the data receiver 60 and the code detector 62. In the data receiver 10 60, the spreading code is correlated with the baseband signal to extract the data signal which is forwarded for further processing. The received baseband signal is also forwarded to the code detector 62 which detects the access code or the 15 short code from the subscriber unit 16 and adjusts the timing of the spreading code generator 58 to establish a communication channel 18.

In the transmitter section 52 of the base station 14, the 20 transmit spreading code generator 64 outputs a spreading code to the data transmitter 66 and the pilot code transmitter 68. The pilot code transmitter 68 continuously transmits the periodic pilot code. The data transmitter 66 transmits the short code detect indication and access code detect 25 acknowledgment after the code detector 62 has detected the short code or the access code respectively. The data transmitter also sends other message and data signals. The signals from the data transmitter 66 and the pilot code

-22-

transmitter 68 are combined and up-converted by the RF transmitter 70 for transmission to the subscriber units 16.

A block diagram of the subscriber unit 16 is shown in Figure 10. Briefly described, the subscriber unit 16 comprises a receiver section 72, a transmitter section 74 and a diplexer 84. An RF receiver 76 receives and down-converts the RF signal received from the diplexer 84. A pilot code detector 80 correlates the spreading code with the baseband signal to acquire the pilot code transmitted by the base station 16. In this manner, the pilot code detector 80 maintains synchronization with the pilot code. The receiver spreading code generator 82 generates and outputs a spreading code to the data receiver 78 and the pilot code detector 80. The data receiver 78 correlates the spreading code with the baseband signal to process the short code detect indication and the access code detect acknowledgment transmitted by the base station 16.

The transmitter section 74 comprises a spreading code generator 86 which generates and outputs spreading codes to a data transmitter 88 and a short code and access code transmitter 90. The short code and access code transmitter 90 transmits these codes at different stages of the power ramp-up procedure as hereinbefore described. The signals output by the data transmitter 88 and the short code and access code transmitter 90 are combined and up-converted by the RF transmitter 92 for transmission to the base station 14. The timing of the receiver spreading code generator 82 is adjusted by the pilot code detector 80 through the acquisition

-23-

process. The receiver and transmitter spreading code generators 82, 86 are also synchronized.

An overview of the ramp-up procedure in accordance with the preferred current invention is summarized in Figures 11A and 11B. The base station 14 transmits a pilot code while searching for the short code (step 200). The subscriber unit 16 acquires the pilot code transmitted from the base station 14 (step 202), starts transmitting a short code starting at a minimum power level P_0 which is guaranteed to be less than the required power, and quickly increases transmission power (step 204). Once the received power level at the base station 14 reaches the minimum level needed for detection of the short code (step 206) the base station 14 acquires the correct phase of the short code, transmits an indication of this detection, and begins searching for the access code (step 208). Upon receiving the detection indication, the subscriber unit 16 ceases transmitting the short code and starts transmitting an access code. The subscriber unit 16 initiates a slow ramp-up of transmit power while sending the access code (step 210). The base station 14 searches for the correct phase of the access code by searching only one phase out of each short code length portion of the access code (step 212). If the base station 14 searches the phases of the access code up to the maximum round trip delay and has not detected the correct phase, the search is repeated by searching every phase (step 214). Upon detection of the correct phase of the access code by the base station 14, the base station 14 sends an acknowledgment to the subscriber unit 16 (step 216). Reception

-24-

of the acknowledgment by the subscriber unit 16 concludes the ramp-up process. A closed loop power control is established, and the subscriber unit 16 continues the call setup process by sending related call setup messages (**step 218**).

5 An alternative embodiment of the present invention in the reestablishment of a communication link will be described with reference to **Figure 12**. The propagation of certain signals in the establishment of a communication channel 318 between a base station 314 and a plurality of subscriber units 316 is shown. The forward pilot signal 320 is transmitted from the
10 base station 314 at time t_0 , and is received by a subscriber unit 316 after a propagation delay Δt . To be acquired by the base station 314 the subscriber unit 316 transmits an access signal 322 which is received by the base station 314 after a
15 further propagation delay of Δt . Accordingly, the round trip propagation delay is $2\Delta t$. The access signal 322 is transmitted epoch aligned to the forward pilot signal 320, which means that the code phase of the access signal 322 when transmitted is identical to the code phase of the received
20 forward pilot signal 320.

The round trip propagation delay depends upon the location of a subscriber unit 316 with respect to the base station 314. Communication signals transmitted between a subscriber unit 316 located closer to the base station 314
25 will experience a shorter propagation delay than a subscriber unit 316 located further from the base station 314. Since the base station 314 must be able to acquire subscriber units 316 located at any position within the cell 330, the base station

-25-

314 must search all code phases of the access signal corresponding to the entire range of propagation delays of the cell 330.

5 Referring to **Figure 13**, the tasks associated with initial acquisition of a subscriber unit 316 by a base station 314 are shown. When a subscriber unit 316 desires the establishment of a channel 318 with a base station 314 with which it has never established a channel, the subscriber unit 316 has no knowledge of the two-way propagation delay. Accordingly, the
10 subscriber unit 316 enters the initial acquisition channel establishment process.

The subscriber unit 316 selects a low initial power level and zero code phase delay, (epoch aligning the code phase of the transmitted access signal 322 to the code phase of the
15 received forward pilot signal 320), and commences transmitting the access signal 322 while slowly (0.05-0.1 dB/msec) ramping-up transmission power (**step 400**). While the subscriber unit 316 is awaiting receipt of the confirmation signal from the base station 314, it varies the code phase delay in
20 predetermined steps from zero to the delay corresponding to the periphery of the cell 330, (the maximum code phase delay), allowing sufficient time between steps for the base station 314 to detect the access signal 322 (**step 402**). If the subscriber unit 316 reaches the code phase delay corresponding
25 to the periphery of the cell 330, it repeats the process of varying the code phase delay while continuing the slow power ramp-up (**step 402**).

-26-

In order to acquire subscriber units 316 desiring access, the base station 314 continuously transmits a forward pilot signal 320 and attempts to detect the access signals 322 from subscriber units 316 (step 404). Rather than test for access signals 322 at all code phase delays within the cell 330 as with current systems, the base station 314 need only test code phase delays centered about the periphery of the cell 330.

The base station 314 detects the access signal 322 (step 406) when the subscriber unit 316 begins transmitting with sufficient power at the code phase delay which makes the subscriber unit 316 appear to be at the periphery of the cell 330, thereby "virtually" locating the subscriber unit 316 at the periphery of the cell 330. The base station 314 then transmits a signal to the subscriber unit 316 which confirms that the access signal 322 has been received (step 408) and continues with the channel establishment process (step 410).

Once the subscriber unit 316 receives the confirmation signal (step 412), it ceases the ramp-up of transmission power, ceases varying the code phase delay (step 414) and records the value of the code phase delay for subsequent re-acquisitions (step 416). The subscriber unit 316 then continues the channel establishment process including closed-loop power transmission control (step 418).

On subsequent re-acquisitions when a subscriber unit 316 desires the establishment of a channel 318 with a base station 314, the subscriber unit 316 enters the re-acquisition channel establishment process shown in Figure 14. The subscriber unit 316 selects a low initial power level and the code phase delay

-27-

recorded during the initial acquisition process, (shown in **Figure 13**), and commences continuously transmitting the access signal **322** while quickly (1 dB/msec) ramping-up transmission power (**step 420**). While the subscriber unit **316** is awaiting receipt of the confirmation signal from the base station **314**, it slightly varies the code phase delay of the access signal **322** about the recorded code phase delay, allowing sufficient time for the base station **314** to detect the access signal **322** before changing the delay (**step 422**). The base station **314** as in **Figure 13**, transmits a forward pilot signal **320** and tests only the code phase delays at the periphery of the cell **330** in attempting to acquire the subscriber units **316** within its operating range (**step 424**). The base station **314** detects the access signal **322** when the subscriber unit **316** transmits with sufficient power at the code phase delay which makes the subscriber unit **316** appear to be at the periphery of the cell **330** (**step 426**). The base station **314** transmits a signal to the subscriber unit **316** which confirms that the access signal **322** has been received (**step 428**) and continues with the channel establishment process (**step 430**).

When the subscriber unit **316** receives the confirmation signal (**step 432**) it ceases power ramp-up, ceases varying the code phase delay (**step 434**) and records the present value of the code phase delay for subsequent re-acquisitions (**step 436**). This code phase delay may be slightly different from the code phase delay initially used when starting the re-acquisitions process (**step 422**). The subscriber unit **316** then continues the channel establishment process at the present

-28-

power level (**step 438**). If a subscriber unit **316** has not received a confirmation signal from the base station **314** after a predetermined time, the subscriber unit **316** reverts to the initial acquisition process described in **Figure 13**.

5 The effect of introducing a code phase delay in the Tx **320** and Rx **322** communications between the base station **314** and a subscriber unit **316** will be explained with reference to **Figures 15A** and **15B**. Referring to **Figure 15A**, a base station **460** communicates with two subscriber units **462**, **464**. The
10 first subscriber unit **462** is located 30 km from the base station **460** at the maximum operating range. The second subscriber unit **464** is located 15 km from the base station **460**. The propagation delay of Tx and Rx communications between the first subscriber unit **462** and the base station **460**
15 will be twice that of communications between the second subscriber unit **464** and the base station **460**.

Referring to **Figure 15B**, after an added delay value **466** is introduced into the Tx PN generator of the second subscriber unit **464** the propagation delay of communications
20 between the first subscriber unit **462** and the base station **460** will be the same as the propagation delay of communications between the second subscriber unit **464** and the base station **460**. Viewed from the base station **460**, it appears as though the second subscriber unit **464** is located at the virtual range
25 **464'**.

Referring to **Figure 16**, it can be seen that when a plurality of subscriber units **S1 - S7** are virtually relocated **S1' - S7'** to the virtual range **475**, the base station **B** must

-29-

only test the code phase delays centered about the virtual range 475.

Utilizing the present invention, a subscriber unit 316 which has achieved a sufficient power level will be acquired by the base station 314 in approximately 2 msec. Due to the shorter acquisition time, the subscriber unit 316 can ramp-up at a much faster rate, (on the order of 1 dB/msec), without significantly overshooting the desired power level. Assuming the same 20 dB power back-off, it would take the subscriber unit 316 approximately 20 msec to reach the sufficient power level for detection by the base station 314. Accordingly, the entire duration of the re-acquisition process of the present invention is approximately 22 msec, which is an order of magnitude reduction from prior art reacquisition methods.

A subscriber unit 500 made in accordance with this embodiment of the present invention is shown in **Figure 17**. The subscriber unit 500 includes a receiver section 502 and a transmitter section 504. An antenna 506 receives a signal from the base station 314, which is filtered by a band-pass filter 508 having a bandwidth equal to twice the chip rate and a center frequency equal to the center frequency of the spread spectrum system's bandwidth. The output of the filter 508 is down-converted by a mixer 510 to a baseband signal using a constant frequency (F_c) local oscillator. The output of the mixer 510 is then spread spectrum decoded by applying a PN sequence to a mixer 512 within the PN Rx generator 514. The output of the mixer 512 is applied to a low pass filter 516 having a cutoff frequency at the data rate (F_b) of the PCM

-30-

data sequence. The output of the filter 516 is input to a coder/decoder (codec) 518 which interfaces with the communicating entity 520.

A baseband signal from the communicating entity 520 is pulse code modulated by the codec 518. Preferably, a 32 kilobit per second adaptive pulse code modulation (ADPCM) is used. The PCM signal is applied to a mixer 522 within a PN Tx generator 524. The mixer 522 multiplies the PCM data signal with the PN sequence. The output of the mixer 522 is applied to low-pass filter 526 whose cutoff frequency is equal to the system chip rate. The output of the filter 526 is then applied to a mixer 528 and suitably up-converted, as determined by the carrier frequency F_c applied to the other terminal. The up-converted signal is then passed through a band-pass filter 530 and to a broadband RF amplifier 532 which drives an antenna 534.

The microprocessor 536 controls the acquisition process as well as the Rx and Tx PN generators 514, 524. The microprocessor 536 controls the code phase delay added to the Rx and Tx PN generators 514, 524 to acquire the forward pilot signal 320, and for the subscriber unit 500 to be acquired by the base station 314, and records the code phase difference between these PN generators. For re-acquisition the microprocessor 536 adds the recorded delay to the Tx PN generator 524.

The base station 314 uses a configuration similar to the subscriber unit 316 to detect PN coded signals from the subscriber unit 500. The microprocessor (not shown) in the

-31-

base station 314 controls the Rx PN generator in a similar manner to make the code phase difference between Rx PN generator and the Tx PN generator equivalent to the two-way propagation delay of the subscriber unit's 316 virtual location. Once the base station 314 acquires the access signal 322 from the subscriber unit 316, all other signals from the subscriber unit 316 to the base station 314 (traffic, pilot, etc.) use the same code phase delay determined during the acquisition process.

It should be noted that although the invention has been described herein as the virtual locating of subscriber units 316 at the periphery of the cell 330 the virtual location can be at any fixed distance from the base station 314.

Referring to **Figure 18**, the tasks associated with initial acquisition of a "never-acquired" subscriber unit 316 by a base station 314 in accordance with an alternative embodiment of the present invention are shown. The subscriber unit 316 continuously transmits an epoch aligned access signal 322 to the base station 314 (**step 600**) when the establishment of a channel 318 is desired. While the subscriber unit 316 is awaiting the receipt of a confirmation signal from the base station 314, it continuously increases the transmission power as it continues transmission of the access signal 322 (**step 602**).

To detect subscriber units which have never been acquired, the base station 314 transmits a forward pilot signal 320 and sweeps the cell by searching all code phases corresponding to the entire range of propagation delays of the

-32-

cell (step 604) and detects the epoch aligned access signal 322 sent from the subscriber unit 316 after the transmission has achieved sufficient power for detection (step 606). The base station 314 transmits a signal to the subscriber unit 316 (step 608) which confirms that the access signal 322 has been received. The subscriber unit 316 receives the confirmation signal (step 610) and ceases the increase in transmission power (step 612).

The base station 314 determines the desired code phase delay of the subscriber unit 316 by noting the difference (step 614) between the Tx and Rx PN generators 524, 514 after acquiring the subscriber unit 316. The desired code phase delay value is sent to the subscriber unit 316 (step 616) as an OA&M message, which receives and stores the value (step 618) for use during re-acquisition, and continues with the channel establishment process (steps 622 and 624).

Referring to Figure 19, an alternative method of fast reacquisition in accordance with the present invention is shown. When a communication channel must be reestablished between the subscriber unit 316 and the base station 314, the subscriber unit 316 transmits the access signal 322 with the desired code phase delay as in the preferred embodiment.

With all of the previously acquired subscriber units 316 at the same virtual range, the base station 314 need only search the code phase delays centered about the periphery of the cell to acquire the access signals 322 of such subscriber units 316 (step 630). Thus, a subscriber unit 316 may ramp-up power rapidly to exploit the more frequent acquisition

-33-

opportunities. The subscriber unit 316 implements the delay the same way as in the preferred embodiment. The base station 314 subsequently detects the subscriber unit 316 at the periphery of the cell (step 636), sends a confirmation signal to the subscriber unit (step 637) and recalculates the desired code phase delay value, if necessary. Recalculation (step 638) compensates for propagation path changes, oscillator drift and other communication variables. The subscriber unit 316 receives the confirmation signal from the base station 316 (step 639).

The base station 314 sends the updated desired code phase delay value to the subscriber unit 316 (step 640) which receives and stores the updated value (step 642). The subscriber unit 316 and the base station 314 then continue the channel establishment process communications (steps 644 and 646).

Note that the alternative embodiment requires the base station to search both the code phase delays centered on the periphery of the cell to re-acquire previously acquired subscriber units and the code phase delays for the entire cell to acquired subscriber units which have never been acquired.

Referring to **Figure 20**, the tasks associated with initial acquisition of a never-acquired subscriber unit 316 by a base station 314 in accordance with a second alternative embodiment of the present invention are shown. In the embodiment shown in **Figure 18**, when a never-acquired subscriber unit 316 is acquired, the access signal 320 remains epoch aligned to the forward pilot signal 320. In this embodiment, the base

-34-

station 314 and subscriber unit 316 change the code phase alignment of the access signal 322 from epoch aligned to delayed, (by the code phase delay), to make the subscriber unit 316 appear at the periphery of the cell. This change is performed at a designated time.

Steps 700 through 718 are the same as the corresponding steps 600 through 618 shown in Figure 18. However, after the base station 314 sends the desired delay value to the subscriber unit 316 (step 716) the base station 314 sends a message to the subscriber unit 316 to switch to the desired delay value at a time referenced to a sub-epoch of the forward pilot signal 320 (step 720). The subscriber unit 316 receives this message (step 722), and both units 314, 316 wait until the switchover time is reached (steps 724, 730). At that time, the base station 314 adds the desired delay value to its Rx PN operator (step 732) and the subscriber unit 316 adds the same desired delay value to its Tx PN generator (step 726). The subscriber unit 316 and the base station 314 then continue the channel establishment process communication (step 728, 734).

Although the invention has been described in part by making detailed reference to the preferred embodiment, such detail is intended to be instructive rather than restrictive. It will be appreciated by those skilled in the art that many variations may be made in the structure and mode of operation without departing from the scope of the invention as disclosed in the teachings herein.

AMENDED SHEET

-35-

What is claimed is:

1. A method for controlling transmission power during the establishment of communications between a base station and at least one subscriber unit, the method comprising:

5 transmitting a short code from said subscriber unit at an initial predetermined power level;

continuously increasing said power level at a predetermined first ramp-up rate;

detecting said short code at said base station when a sufficient power for detection is achieved;

10 transmitting a signal from said base station confirming that said short code has been detected;

receiving said confirmation signal at said subscriber unit; and

15 ceasing said predetermined first power level ramp-up rate when said confirmation signal is received.

2. The method of claim 1 wherein said initial predetermined power level is lower than the power level required for detection by said base station.

20 3. The method of claim 2 further including continuously increasing the power level of said short code at a second predetermined rate after receiving said confirmation signal, said second rate being less than said first rate.

25 4. The method of claim 3 wherein said first rate is approximately 1.0dB/msec and said second rate is approximately 0.05dB/msec.

5. The method of claim 3 further including transmitting from said subscriber unit an access code at a second power ramp-up rate after said confirmation signal is received.

-36-

6. The method of claim 5 wherein the duration of said short code is less than the duration of said access code.
7. The method of claim 5 wherein the duration of said access code is an even multiple of the duration of said short code.
- 5 8. The method of claim 5 wherein the beginning of said access code is aligned with the beginning of said short code.
9. The method of claim 5 further including detecting, by said base station, said access code and searching for the beginning of said access code.
- 10 10. The method of claim 9 wherein said short and access codes comprise a plurality of chips and wherein said base station searches every Nth chip of said access code; where N is the number of chips in said short code.
11. The method of claim 10 further including ceasing, after
15 a predetermined duration, the search of every Nth chip when the beginning of said access code has not be determined.
12. The method of claim 11 wherein said predetermined duration is equivalent to the round trip delay of a signal sent to a subscriber unit at the maximum operating range of the system.
- 20 13. The method of claim 11 further including searching every chip of said access code after said predetermined duration.
14. The method of claim 11 further including transmitting an acknowledgment signal from said base station when the beginning of said access code has been detected by said base station.
- 25 15. The method of claim 12 further including ceasing the continuous increase in transmission power from said subscriber

-37-

unit upon the receipt of an acknowledgment signal by said subscriber unit.

16. The method of claim 1 further including detecting at said base station, the correct phase of said short code when the signal achieves sufficient power for detection by said base station.

17. A network for communicating between a base station and at least one subscriber unit, both said base station and subscriber unit having means for transmitting and detecting signals, the network including a system for initial power control comprising:

said subscriber unit comprising:

means for selectively transmitting a short code at a selected transmission power level;

means for detecting a confirmation signal from said base station; and

control means, responsive to said detecting means, for varying said transmission power level; wherein said control means continuously increases said transmission power level at a first rate prior to the receipt of said confirmation signal and continuously increases said transmission power level at a second rate after the receipt of said confirmation signal, said second rate being less than said first rate; and

said base station comprising:

means for detecting said short code; and

transmission means, responsive to said detecting means, for transmitting a confirmation signal to said subscriber unit when said short code is detected.

18. The system of claim 17 wherein said short code is initially transmitted at a power level lower than the power level required for detection by said base station.

-38-

19. The system of claim 18 wherein said first rate is approximately 1.0dB/msec and said second rate is approximately 0.05dB/msec.

5 20. The system of claim 18 wherein said selectively transmitting means transmits an access code at said second rate after the receipt of said confirmation signal.

21. The system of claim 20 wherein the duration of said short code is less than the duration of said access code.

10 22. The system of claim 20 wherein the duration of said access code is an even multiple of the duration of said short code.

23. The system of claim 20 wherein the beginning of said access code is aligned with the beginning of said short code.

15 24. The system of claim 20 wherein the base station detecting means detects said access code and searches for the beginning of said access code.

25. The system of claim 24 wherein said short and access codes comprise a plurality of chips and wherein said base station detecting means searches every Nth chip of said access code; where N is the number of chips in said short code.

20 26. The system of claim 25 wherein said base station detecting means ceases the search of every Nth chip, after a predetermined duration, when the beginning of said access code has not been determined.

25 27. The system of claim 26 wherein said predetermined duration is equivalent to the round trip delay of a signal sent to a subscriber unit at the maximum operating range of the system.

-39-

28. The system of claim 18, the base station further including means for detecting the correct phase of said short code when said short code achieves sufficient power for detection.

5 29. A network for communicating between a base station and at least one subscriber unit, both said base station and subscriber unit having means for transmitting and detecting signals, including a system for reducing the reacquisition time of said subscriber unit by said base station, the system
10 comprising:

the base station including:

means for detecting an access signal from said subscriber unit at a sufficient power level and proper delay;

15 means for generating a confirmation signal for transmission to said subscriber unit in response to said access signal; and

the subscriber unit including:

20 means for generating said access signal for transmission to said base station;

means for varying the transmission power and changing the delay of said transmitted access signal;

means for detecting said confirmation signal; and

25 means for ceasing the variation in said transmission power and the change in delay when said confirmation signal is received;

wherein said proper delay is a round trip delay associate with a subscriber unit at a fixed distance from said base station.

30 30. The system of claim 29 wherein varying the transmission power is by incrementally increasing the transmission power.

31. The system of claim 30 wherein the fixed distance is the distance to the periphery of the base station's cell.

-40-

32. The system of claim 31 wherein for each incremental increase in transmission power the delay is changed by initially having a zero delay and increasing the delay until the delay associated with the round trip delay to the periphery of the base station's cell is reached.

33. The system of claim 29, the subscriber unit further comprising means for storing the access signal delay when said confirmation signal is received for use in future reacquisitions of said subscriber unit.

34. A method for reducing the reacquisition time of a subscriber unit by a base station in a network for communicating between a base station and at least one subscriber unit; the method comprising:

transmitting an access signal from a subscriber unit at a predetermined power transmission level and phase delay;

varying said transmission power and delay of said access signal until a confirmation signal is received from said base station;

detecting said access signal at said base station when a sufficient power level and proper delay have been achieved;

transmitting a confirmation signal from said base station when said access signal has been detected;

receiving said confirmation signal at said subscriber unit; and

ceasing the variation in transmission power and delay from said subscriber unit when said confirmation signal is received;

wherein said proper delay is a round trip delay associated with a subscriber unit at a fixed distance from the base station.

35. The method of claim 34 wherein varying the transmission power is by incrementally increasing the transmission power.

-41-

36. The method of claim 35 wherein the fixed distance is the distance to the periphery of the base station's cell.

37. The method of claim 36 wherein varying and delaying said access signal further comprises:

5 incrementally increasing said transmission power; and
 increasing the delay from a zero delay to the round trip delay from the base station to a subscriber unit at the periphery of the base station's cell for each incremental increase in transmission power.

10 38. The method of claim 34 further comprising storing the access signal delay when said confirmation signal is received.

39. The method of claim 38 further comprising subsequently reacquiring the subscriber unit after termination of initial communications using said stored delay.

15 40. The method of claim 39 wherein subsequent reacquisition further comprises:

 transmitting a subsequent access signal from said subscriber unit at a predetermined power level and at said stored delay;

20 incrementally increasing the transmission power;
 detecting said subsequent access signal at said base station when a sufficient power level has been achieved;

 transmitting a subsequent confirmation signal from said base station when said access signal has been detected;

25 receiving said subsequent confirmation signal at said subscriber unit; and

 ceasing the incremental increase in transmission power from said subscriber unit when said confirmation signal is received.
