photoperiod, systemic signaling, floral transition, light-dependent protein stability, CONSTANS

Abstract

The transition from vegetative to reproductive growth is controlled by day length in many plant species. Day length is perceived in leaves and induces a systemic signal, called florigen, that moves through the phloem to the shoot apex. At the shoot apical meristem (SAM), florigen causes changes in gene expression that reprogram the SAM to form flowers instead of leaves. Analysis of flowering of *Arabidopsis thaliana* placed the *CONSTANS/FLOWERING LOCUS T (CO/FT)* module at the core of a pathway that promotes flowering in response to changes in day length. We describe progress in defining the molecular mechanisms that activate this module in response to changing day length and the increasing evidence that FT protein is a major component of florigen. Finally, we discuss conservation of FT function in other species and how variation in its regulation could generate different flowering behaviors.

INTRODUCTION

The life cycles of many plants are synchronized to the changing seasons. This response is particularly important at high latitudes, where extreme changes in environmental conditions occur at different times of the year. Perception of changes in day length is one of the major ways in which plants detect the changing seasons. Garner & Allard (24, 25), who were the first to describe this process in detail, referred to it as photoperiodism. These observations captured the imagination

of plant researchers and attempts to explain the underlying mechanisms led to the discovery of fundamental plant processes such as the existence of phytochrome as a photoreceptor, systemic signaling from the leaf to the shoot apex during the initiation of flower development, and the role of circadian rhythms as the timekeeping mechanism. Many influential reviews dealing with these issues have appeared in various *Annual Reviews* series during the past 50 years, and each generation of researchers has approached the same biological problem with the tools available to them (8, 22, 46, 48, 83, 93, 102). This review describes the recent progress made mainly in *Arabidopsis* using the tools of molecular genetics, and it summarizes our current answers to the questions posed by the observations of Garner & Allard (24, 25).

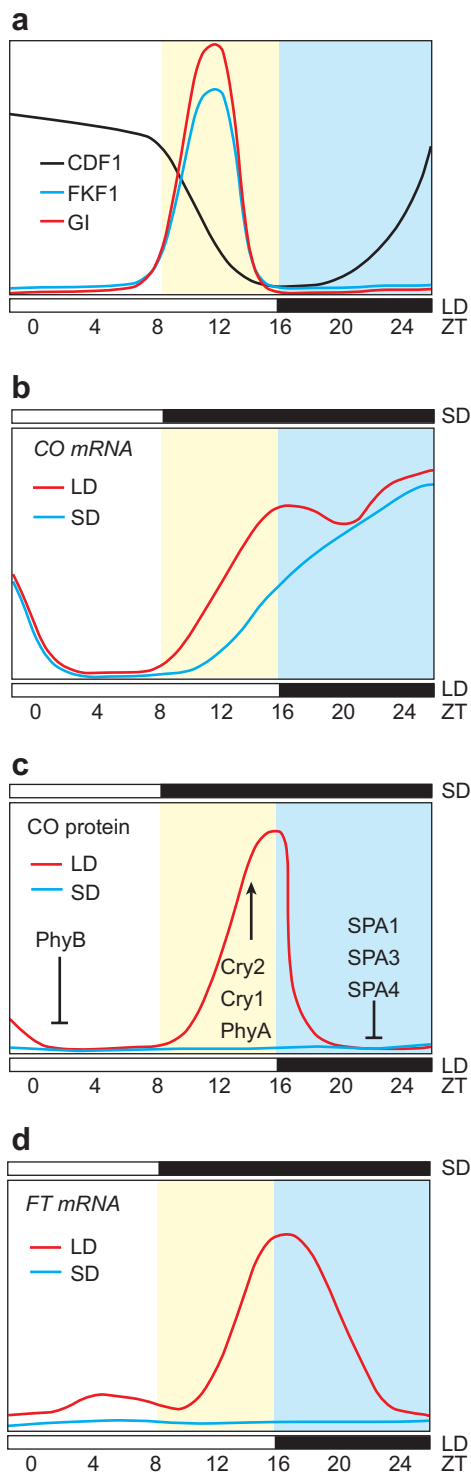

INDUCTION OF FLOWERING BY PHOTOPERIOD IN *ARABIDOPSIS* AND THE EXTERNAL COINCIDENCE MODEL

Genetic approaches applied in *Arabidopsis thaliana* provided insight into the molecular mechanisms controlling photoperiodic responses. Recent reviews have described in detail the results of these approaches (4, 6, 32, 34, 38, 67, 79). *Arabidopsis* is a facultative long-day plant that flowers earlier under long days (LDs) of 16 h of light than under short days (SDs) of 8 or 10 h of light. The photoperiodic pathway mutants *co* (*constans*), *gi* (*gigantea*), *cry2* (*cryptochrome*), *flowering locus d* (*fd*), *flowering locus t* (*ft*), *fe*, and *fwa* flowered later than wild-type plants under LDs but at the same time as wild-type plants under SDs. The sequences of all these genes have now been published, with the exception of *FE* (1, 23, 27, 40, 44, 70, 84, 95), and they were proposed to comprise a single regulatory pathway, called the photoperiodic or long-day pathway, that promotes flowering specifically in response to LDs.

The GI-CO-FT proteins act in this order at the core of the photoperiodic pathway, and their regulation results in *FT* transcription under LDs but not SDs (Figures 1 and 2). *CO* mRNA is present under both LDs and SDs and is regulated by the circadian clock, so that it rises in abundance between 10 h and 12 h after dawn. GI increases *CO* mRNA abundance (62, 78, 85). Under SDs *CO* mRNA accumulates only during the night, whereas under LDs substantial expression is detected toward the end of the day. Furthermore, CO-mediated activation of *FT* transcription occurs at the end of the day under LDs but not under SDs (85). These comparisons

Figure 1

Circadian expression of key components in the photoperiod pathway. (a) GI and CDF1 are circadian clock-controlled positive and negative transcriptional regulators of *CO*, respectively. CDF1 directly binds to AAAG-elements within the *CO* promoter. FKF1 is required for CDF1 degradation toward the middle of the day, thus permitting *CO* mRNA levels to rise. (b) *CO* mRNA expression differs between LDs and SDs such that a biphasic curve is observed only in LDs. (c) Accumulation of CO protein is strongly dependent on the coincidence of light and mRNA expression. CO protein is degraded by a proteasome-dependent mechanism, but it is stabilized toward the end of LDs through the concerted action of CRY2, CRY1, and PhyA. During the night, CO degradation is dependent on the presence of SPA1, SPA3, and SPA4. In the early morning, PhyB negatively regulates CO stability, which counteracts an early peak in CO that could be caused by high *CO* mRNA levels at the end of the night. (d) *FT* mRNA production is a direct result of CO protein accumulation toward the end of LDs. White area: duration of light during LDs and SDs. Yellow area: light in LDs but dark in SDs. suggested that posttranscriptional activation of *CO* may occur only when *CO* mRNA is expressed in the light. Support for this model came from manipulating the circadian rhythm of *CO* mRNA expression using the *toc1-1* mutation or by altering the length of the daily cycle from 24 h. Both of these approaches showed that if *CO* mRNA accumulates in the light under SDs, then *FT* expression and early flowering occur (75, 99).

Under LDs the peak of *CO* mRNA abundance is broader and extends into the light (Figure 1). This response requires the

FLAVIN-BINDING, KELCH REPEAT, F-BOX PROTEIN 1 (FKF1) protein. In *flk1* mutants the abundance of *CO* mRNA in the light at the end of an LD is reduced (36) (Figure 1). *FKF1* encodes the F-box protein subunit of an SCF ubiquitin ligase, suggesting that FKF1 directs the degradation of substrate proteins by catalyzing their ubiquitination. FKF1 interacts with GI *in vivo* and light is required to stabilize their interaction (78). Thus the FKF1-GI complex might target for degradation a negative regulator of *CO* transcription and thereby increase *CO* mRNA levels at the end of the day. Consistent with this idea, *FKF1* and *GI* transcription is also regulated by the circadian clock and their mRNA abundance peaks around the time *CO* transcription rises (Figure 1). The transcription factor CYCLING DOF FACTOR 1 (CDF1) likely plays a part in this negative regulation of *CO*. CDF1 physically interacts with FKF1 and GI (35, 78), and overexpression of CDF1 from the *CaMV 35S* promoter causes late flowering and represses *CO* transcription. HA-CDF1 expressed from the *CDF1* promoter accumulates only early in the day in wild-type plants but persists for longer in *flk1* mutants, consistent with a role for FKF1 in the degradation of CDF1 protein. Chromatin immunoprecipitation data suggest that FKF1, GI, and CDF1 proteins bind the *CO* promoter and that degradation of CDF1 possibly takes place on the DNA at the *CO* locus (78). However, plants in which *CDF1* mRNA levels were severely reduced by *CDF1* double-stranded RNAi exhibited a weak early-flowering phenotype and no increase in *CO* mRNA levels (35). Thus the requirement for CDF1 in regulating *CO* transcription in wild-type plants is relatively weak, perhaps because it is genetically redundant with other repressors of *CO* transcription.

The observation that expression of *CO* mRNA during the night under SDs does not promote flowering suggested that exposure to light activates *CO* function at the posttranscriptional level. Analysis of CO:GFP fusion protein expression demonstrated that this

activation occurs at the level of accumulation of the CO protein (92). In *35S::CO:GFP* plants, GFP is detected in the nucleus when plants are exposed to light, but disappears within a few hours of shifting plants to darkness. Endogenous CO protein is below the level of detection on Western blots, but when expressed from the *CaMV 35S* promoter, CO protein is easily detected. The protein accumulates to highest levels at the end of an LD and falls rapidly in abundance in the dark, whereas in these plants CO mRNA is present at constant levels. Furthermore, the abundance of the protein is increased by application of a proteasome inhibitor, supporting the idea that CO protein is degraded via ubiquitination. These data suggest that turnover of CO protein is increased during the night and at the beginning of the day, but reduced at the end of the day, and therefore that post-transcriptional regulation provides an independent layer of regulation that limits CO activity to the end of the day (**Figure 1**).

The effect of light quality on CO protein levels was then tested in photoreceptor mutants carrying the *35S::CO* transgene (92). These experiments indicated that PhyB is required for the degradation of the protein early in the day.

In contrast, cryptochromes, in particular CRYPTOCHROME 2 (CRY2), as well as PHYTOCHROME A (PhyA), contribute to the stabilization of the protein at the end of the day, although single mutations in these photoreceptors have a small effect on protein abundance, suggesting that the photoreceptors might be functionally redundant (92) (**Figure 1**). The photoreceptors PhyA, CRY2, and CRYPTOCHROME 1 (CRY1) promote CO stability, whereas the photoreceptor PHYTOCHROME B (PhyB) destabilizes CO. These data are in agreement with the flowering times of photoreceptor mutants, because the *cry2* and *phyA* photoreceptor mutants are late flowering, whereas *phyB* mutants are early flowering (63, 99). Finally, degradation of the CO protein likely involves the SUPPRESSOR

OF PHYA-105-1 protein (SPA1). SPA1 was previously shown to act in concert with the E3 ubiquitin ligase CONSTITUTIVE PHOTOMORPHOGENESIS 1 (COP1) to regulate photomorphogenesis. Mutations in *SPA1* cause early flowering under SDs, and this phenotype is enhanced by combining mutations in related *SPA* genes, so that the *spa1 spa3 spa4* triple mutant flowers at the same time under LDs and SDs (49). SPA proteins physically interact with CO both in vitro and in vivo, and mutations in *CO* suppress the early flowering of *spa1* mutants. Also the abundance of the CO protein is markedly increased in a *spa1 spa3 spa4* triple mutant. These results suggest that the SPA proteins are important in mediating the degradation of the CO protein. Factors involved in CO degradation include SPA1 (SUPPRESSOR OF PHYA-105-1), SPA3, and SPA4.

The analysis of the temporal regulation of *CO* mRNA and protein suggests that the photoperiodic flowering response in *Arabidopsis* is controlled by an external coincidence model similar to that originally proposed by Bünning (14) and Pittendrigh & Minis (68). According to this model, the photoperiodic response is triggered when the product of an enzymic reaction reaches a threshold level. The abundance of the substrate of this reaction exhibits a circadian rhythm, and the enzyme that converts the substrate to the product is active in the light but reverts to an inactive state in the dark. Therefore, the photoperiodic response would only occur when exposure to light, which activates the enzyme, coincides with the peak in the circadian rhythm of the substrate. This model has striking similarities to the regulation of CO, in which the circadian rhythm in the substrate is represented by the rhythm in *CO* mRNA abundance, and inactivity of the enzyme in the dark is represented by the degradation of CO protein in darkness. Although at first sight the *CO* system appears even simpler than the original model because it includes only one component, the reality is likely much more complex. For example, external coincidence between circadian

regulation and exposure to light probably also acts on other components within the pathway (**Figure 2**). FKF1 binds flavin mononucleotide, the chromophore of the photoreceptor phototropin, and according to spectroscopic data FKF1 forms photointermediates similar to those formed by phototropin (36). This observation suggests that FKF1 activity is influenced by light. Furthermore, *GI* transcription is regulated by the circadian clock and activated by light and the GI protein requires light for the interaction with FKF1. Therefore, exposure to light can influence the activity of *GI* at the transcriptional and posttranscriptional level (62, 78). Thus, although our understanding of *CO* regulation is most advanced, similar interactions between light and circadian regulation likely control the activity of multiple components in the photoperiodic pathway (**Figure 2**).

ACTIVATION OF *FT* TRANSCRIPTION BY *CO*

In general, understanding the biochemical function of *CO* has not advanced as rapidly as understanding its regulation and general contribution to photoperiodic responses. Genetic analysis placed *FT* downstream of *CO* and experiments performed with a chemically inducible *CO:GR* fusion protein suggested that it plays a direct role in *FT* transcriptional activation (40, 44, 47, 77, 85).

CO contains two distinct, well-defined protein domains called the B-box (Zinc finger domain) and the CCT (CONSTANS, *CO-LIKE*, TIMING OF CAB 1) domain (26, 70, 74). Zinc-binding B-boxes are found in many animal transcription factors (89); one or two B-boxes are usually associated with a RING and a coiled-coil domain to form the so-called tripartite motif (11), which has been implicated in protein-protein interactions rather than DNA binding. The amino-terminal B-box of *CO* is the founding member of a plant-specific B-box subvariant, which occurs either as a single or duplicated domain, often but not always in combination with a

CCT domain. *CO* and 16 related *COL* (*CO-LIKE*) proteins in *Arabidopsis* carry the combination of B-box and CCT domains (26, 74), whereas additional proteins contain the CCT domain but no B-boxes.

Difficulty in demonstrating direct DNA binding led to the suggestion that *CO* is recruited to DNA by an unidentified protein partner (85). As *CO* B-box:Gal4 DNA binding domain fusion proteins transactivate gene expression in yeast, the role of *CO* may be to add transactivation function to a protein complex (7). A recent alternative hypothesis is that *CO* requires protein partners to enhance the affinity of an otherwise weak DNA binding activity of the CCT domain. This hypothesis is based on the finding that the CCT domain of *CO* and several *Arabidopsis* or tomato *COLs* interact with subunits of the eukaryotic CCAAT-box binding complex (7, 94) and that the CCT domain shows structure and sequence homology to the sequence-specific DNA binding domain of HAP2 (94).

Metazoan CBF/NFY and yeast HAP complexes are formed by three and four distinct subunits, respectively (57). The preassembled HAP3 and HAP5 dimer recruits the structurally unrelated HAP2 subunit to the complex. None of the subunits alone can stably bind DNA, but the preassembled trimeric complex stably associates with canonical CCAAT box *cis* elements. Amino acid residues required for HAP2 interaction with HAP3/5 and CCAAT-element recognition are most conserved in the CCT domain. Furthermore, mutations that impair the activity of CCT domain-containing proteins affect these conserved amino acids (94).

Genetic evidence that HAP proteins regulate *FT* transcription has been difficult to obtain because in *Arabidopsis* approximately 10 genes encode each of the different subunits (20, 28). Nevertheless, perturbation of subunit stoichiometry by overexpression of HAP2 or HAP3 subunits strongly delays flowering of *Arabidopsis*, and this effect can be counterbalanced by increasing *CO* concentration (94).

Is *FT* the only gene activated by CO? Studies using *35S::CO:GR* transgenic plants, in which CO activity can be induced with dexamethasone, initially identified that *FT* and several other genes, including *SOC1* (*SUPPRESSOR OF OVEREXPRESSION OF CONSTANS*), are directly activated by CO. However, expression of CO from the *CaMV 35S* promoter in this experiment, at a higher level than in wild-type plants and in a broader set of cell types, may have led to the activation of genes that are not regulated by CO in wild-type plants. Microarray analysis comparing genes expressed in leaves of wild-type, *co*, and *ft* plants shifted from SDs to LDs identified *FT* as the only gene whose expression was higher under LDs than under SDs in wild-type plants but not in *co* mutants (95). Also, an mRNA null allele of *FT* (*ft-10*) apparently suppressed the early-flowering phenotype caused by overexpression of *CO* from the *CaMV 35S* promoter (100). These experiments suggest that *FT* is the only gene activated by CO and the only gene that promotes flowering downstream of CO. However, the *FT*-like gene, *TWIN SISTER OF FT* (*TSF*), also appears to be activated by CO and promotes flowering (97). So far these observations have not been completely reconciled, but they suggest that CO probably activates at least the expression of *FT* and *TSF* in leaves (Figure 3).

CLASSICAL STUDIES DEMONSTRATED THE INVOLVEMENT OF SYSTEMIC SIGNALING IN PHOTOPERIODIC FLOWERING

Photoperiod perception takes place predominantly in expanded leaves. These leaves evolved to absorb light during photosynthesis and do so more effectively than the SAM, the site of organ formation, which is often shaded by newly formed leaves. Studies performed from the 1930s onward led to the proposal that one or more mobile signals synthesized in the leaves are transported through the phloem

to the SAM and that perception of this mobile signal(s) causes the meristem to change from vegetative development to reproductive development (102). The nature of the signal was further characterized in different plant species over many years. Once induced, the synthesis and effectiveness of the leaf signal can be astonishingly persistent. In *Perilla* spp., successive grafting of an induced leaf to a non-induced shoot could be successfully repeated with the same leaf up to seven times over a period of three months (43). Furthermore, floral induction across interspecies grafts has been reported and long-day and short-day plants are capable of inducing plants of the other response type to flower, suggesting that the floral stimulus appears to be the same or at least functionally equivalent in both types. These experiments supported the hypothesis that a flowering hormone, termed florigen (15), or the floral stimulus, exists in plants and moves from its site of production in the source leaves through the phloem toward the SAM and potentially other sink tissues. None of the classical phytohormones appear to correspond to the definition of a universal floral stimulus, although particularly in *Lolium* spp. a strong argument has been made for gibberellins (GAs) acting as a systemic floral signal (42).

ANALYSIS OF THE SPATIAL REGULATION OF THE PHOTOPERIODIC PATHWAY LINKS FT PROTEIN AND FLORIGEN

The connection between the florigen hypothesis and the *CO/FT* module became apparent when the tissues in which *CO* and *FT* act to regulate flowering were identified. In young plants, *CO* and *FT* are expressed in phloem companion cells, particularly in those of the distal minor veins of source leaves (3, 86). For *FT* this seems to be the only site of expression; however, because of the difficulty in detecting the endogenous transcript by in situ hybridization, these data rely only on promoter reporter gene studies and therefore

Florigen: compound produced in the leaf that moves through the phloem to the shoot apex to induce flowering

Figure 3

FLOWERING LOCUS T (FT) as a systemic signal. (a) Coincidence of *CONSTANS* (CO) mRNA accumulation and light at the end of long days (LDs) stabilizes the CO protein. CO then allows transcription of *FT* and *TWIN SISTER OF FT* (*TSF*) in the phloem companion cells within the distal part of the leaf. FT protein is uploaded into the sieve elements either by diffusion through plasmodesmata or by an unidentified active transport mechanism (*white circle*). The similarity between FT and TSF proteins suggests they behave similarly, but no evidence for movement of the TSF protein has been presented. (b) Long-distance transport of FT toward sink tissues occurs in the phloem translocation stream. FT may associate with other as yet unknown factors (X) during this step. (c) FT unloading from the phloem and transport within the apex probably involves cell-to-cell transport through plasmodesmata. The yellow area indicates a possible gradient of FT and TSF protein distribution in the shoot apical meristem (SAM). Whether diffusion or directed active transport is involved is unclear. Induction of *SUPPRESSOR OF OVEREXPRESSION OF CONSTANS* (*SOC1*) is the first detectable event in the inflorescence meristem (IM) and depends on the presence of FT and the bZIP transcription factor FLOWERING LOCUS D (FD), but whether these directly activate *SOC1* transcription is unknown. FT and FD interact physically and the complex is directly involved in *APETALA 1* (*AP1*) transcriptional activation, which occurs during the formation of the first floral bud. AP1 directly represses *SOC1* in the floral meristem (FM). TSF protein might follow the same systemic path toward the SAM as does FT. In addition, promoter *TSF::GUS* fusions indicate that the *TSF* transcript could be directly produced in cells at the periphery of the SAM. CC, companion cells; SE, sieve elements; boxes, mRNA; circles, protein; solid black arrows, experimentally confirmed interconnection; dotted arrows, inferred interconnection.

require further validation (86). In contrast to *FT*, *CO* mRNA is found in the apical regions above the protophloem and expression is less restricted to the phloem tissue in younger leaves (3, 82). However, CO protein stability is tightly regulated (see above) and studies with *CO::CO::GFP* fusions indicated that the spatial pattern of CO protein is restricted to the phloem (3).

Misexpression of *CO* from heterologous promoters and grafting experiments placed *CO* upstream of a leaf-borne transmissible signal. Thus, expression of *CO* driven by the promoter of *SUC2* in the companion cells throughout the phloem system or by the *GASI* promoter, which is more restricted to the companion cells of the minor veins, generates a graft-transmissible signal that is sufficient to cause a *co* mutant scion to flower (3, 5). In contrast, expression of *CO* in the SAM does not promote flowering (3). Conversely, *FT* causes early flowering when expressed in the phloem or the SAM, and expression of *FT* in either of these tissues promotes the floral transition even in the absence of functional *CO* (3). This observation confirms that *CO* acts upstream in the signaling cascade of *FT* and of the transmissible signal. Indeed, these experiments indicate that the signal must reside downstream of *FT* transcription (3, 86).

Although *FT* is expressed only in the vascular tissue (86), the known biochemical function of FT is in the meristem (1, 95), as is described in detail below. This discrepancy between the spatial pattern of *FT* mRNA expression and the location at which the protein acts provided evidence that a product of *FT* might represent the mobile signal. Two general models emerged to explain the relationship between *FT* and florigen. A direct model proposed that *FT* encodes florigen, so that either *FT* mRNA or protein (or both) move from source leaves to the meristematic tissue. Alternatively, an indirect or relay model proposed that FT activates a transmissible signal in the leaf, and that this moves to the meristem, where it activates

expression of *FT* or an *FT*-like gene. The involvement of an *FT*-like gene would be more plausible because *FT* expression has not been detected at the meristem.

The first experiments performed to test movement of an FT product focused on the *FT* mRNA. Experiments describing movement of *FT* mRNA from the leaf to the meristem using a fusion of a promoter from a heat shock-inducible gene (from soybean *Gmhsp 17.6L*) to *FT* were subsequently retracted (9). Furthermore, *FT* mRNA movement was excluded on the basis of grafting experiments performed in tomato, where mutations in the *FT* ortholog *SINGLE FLOWER TRUSS* (*SFT*) cause late flowering (64). Tomato plants overexpressing *SFT* are early flowering. Grafting a *35S::SFT* donor to an *sft* recipient shoot corrected the mutant phenotype of the recipient shoot. Similarly, *35S::SFT* donors could rescue the late-flowering phenotype of Maryland Mammoth tobacco plants (51, 52). These experiments indicated that the systemic signal must cross the graft junction between these shoots, but careful PCR analysis using RNA of the recipient shoot did not detect *SFT* mRNA that had crossed the graft junction. A similar result was obtained with grafted *Arabidopsis* plants, in which no movement of *FT* mRNA could be detected across graft junctions (18). *FT* mRNA requirement in the apex was also excluded by expressing artificial miRNAs targeted against *FT* in the SAM and the phloem. Expression of artificial miRNAs in the SAM did not alter flowering time, whereas when expressed in the phloem they phenocopied the *ft* mutant (59). Taken together these experiments argue against long-distance movement of *FT* mRNA and against a requirement for the mRNA in the SAM.

In contrast, several results support movement of the FT protein. Expression of FT:GFP fusion proteins from the phloem-specific *SUC2* promoter allowed detection of a GFP signal in the phloem and the SAM region (18), suggesting that the fusion protein can move from the phloem to the meristem. Similar results were obtained

in rice using the rice ortholog of *FT*, *Hd3a* (87). In *Arabidopsis*, the fusion protein but not its mRNA moved toward sink tissue across graft junctions (18). Protein movement was further detected using FT:MYC fusion protein also expressed under the control of the phloem-specific *SUC2* promoter (39). Finally, in grafted *Cucurbita moschata*, protein mass spectrometry was used to show that an FT-like protein moved through the phloem system across graft junctions and that this correlated with flowering (53). Taken together these experiments seem to convincingly demonstrate that FT protein can move long distances through the phloem system and that this is associated with floral induction (**Figure 3**).

However, diffusion of small proteins expressed in companion cells into the sieve element and subsequent transport toward sink tissues may be a general phenomenon, such that movement of a small (20 kDa) protein such as FT may be the expected result (37, 56, 66). Therefore, demonstrating movement of the FT protein is not sufficient to prove that it acts as a transmissible signal, but rather evidence that movement of FT protein is necessary for flowering to occur is required. Such evidence was provided by several experiments. When expressed in the phloem, FT protein fused to a fluorescent protein is impaired in its ability to complement *ft* mutations. Although FT:GFP complements an *ft* mutation when expressed in the SAM or in the major veins from the *SUC2* promoter, its expression in the minor veins of the leaves from the *GAS1* promoter does not complement the mutation (18). This is in contrast to *GAS1::FT*, which does complement *ft*. Furthermore, *GAS1::FT:GFP* plants exhibit altered gene expression patterns in the leaves similar to those caused by *35S::FT* (88). Therefore FT:GFP is active in the leaves of *GAS1::FT:GFP* plants. These experiments suggested that FT movement from the minor veins is required to promote flowering, and that this movement is impaired in *GAS1::FT:GFP* plants (18).

Similarly, FT protein fused to three consecutive YFP proteins did not induce earlier flowering of wild-type plants if expressed from the *SUC2* promoter, but did if expressed ubiquitously from the *CaMV 35S* promoter. This experiment suggests that FT:3xYFP is biochemically active but cannot move from the phloem when expressed from the *SUC2* promoter. Because this fusion protein also contained a viral peptidase recognition site, free FT protein could be cleaved from the fusion protein in the presence of the viral peptidase. Expression of the viral peptidase from the *SUC2* promoter released free FT protein, which induced earlier flowering of wild-type plants (59). This result suggests that movement of free FT but not FT:3xYFP induces early flowering of these plants.

Finally, FT protein was engineered for efficient targeting to the nucleus and a MYC epitope-tag was added (MYC:NLS:FT) (39). Expression of this fusion protein from the *SUC2* promoter in an *ft-10* mutant did not affect the flowering time of the mutant, whereas when expressed from the *CaMV 35S* promoter it caused extreme early flowering. *SUC2::MYC:FT ft-10* plants were early flowering and MYC:FT protein could be detected beyond the vascular tissue in the meristem region, whereas the late flowering of *SUC2::MYC:NLS:FT ft-10* plants correlated with reduced movement of the protein beyond the phloem (39). Taken together, all these experiments based on different approaches provide evidence that movement of FT protein is required for the induction of flowering and that there is no need to postulate an intermediate signal acting between FT activity in the leaf and flowering at the SAM.

Although the experiments described above demonstrate that FT protein movement is required for flowering, they do not unequivocally show that FT protein and florigen are equivalent. For example, a second signal, perhaps induced by expression of *FT* in the leaf, might move along with FT protein. If this second signal were required to optimize movement of FT or to increase the efficiency of

the system, then its requirement might be bypassed by direct expression of *FT* in the meristem. Therefore, the possibility that FT protein acts together with a second mobile component cannot be formally excluded, and active florigen could still be a mixture of substances of which FT protein is only a part.

THE ROLE OF FT IN THE SHOOT APICAL MERISTEM

The developmental program that initiates flower development occurs at the apical meristem after synthesis of FT in the leaves and its transport through the phloem system, but what is the function of FT at the SAM? A breakthrough in this area came from the demonstration that FT interacts in the yeast two-hybrid system with the bZIP transcription factor FLOWERING LOCUS D (FD) (1, 95). Furthermore, mutations in *FD* cause late flowering (47), and *fd* mutations suppress

the early flowering of *35S::FT* plants (1, 95). *FD* mRNA is strongly expressed at the SAM, suggesting that this is the major site of FD action, although it is also present at the root meristem and at lower levels throughout the plant (1, 95) (Figure 4).

The FT/FD heterodimer is involved in the activation of the floral meristem identity genes *APETALA 1* (*AP1*) and *FRUITFUL* (*FUL*) at the shoot apex. Occurrence of *AP1* at the apex is strongly delayed in *fd* mutants (95) and abolished in either *fd lfy* or *ft lfy* double mutant plants, indicating that the FT/FD complex acts redundantly with *LFY* to activate *AP1* (1, 95). Whereas *lfy* mutant plants form abnormal flowers, introduction of either *fd* or *ft* as a second mutation causes the resulting plants to form leaves instead of flowers (1, 76, 95). Furthermore, *FD* overexpression under the control of the *CaMV 35S* promoter causes ectopic expression of *AP1* and *FUL* in leaves of LD-grown but not SD-grown plants,

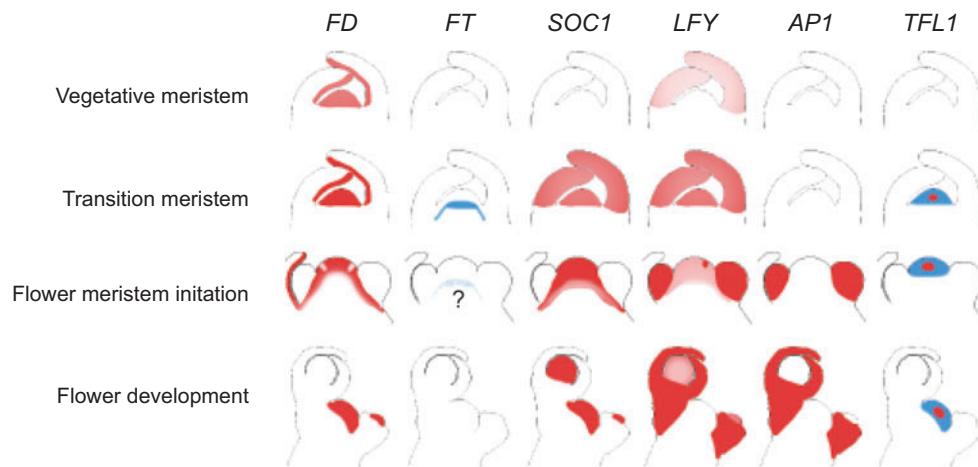

Figure 4

Dynamics of gene expression in the shoot apical meristem upon floral transition. From top to bottom: progression of the apical meristem from a fully vegetative state (vegetative meristem) to a reproductive state (flower development). Two intermediate stages are shown: the transition meristem stage, where morphological changes are not yet visible but induction is taking place, and the flower meristem initiation stage, where the first flower primordia are arising on the flanks of the inflorescence meristem. The mRNA (red) and protein (blue) patterns of key regulators of floral transition are shown. The varying intensity of the color accounts for the expression level of the gene. The question mark referring to *FLOWERING LOCUS T* (*FT*) in later stages indicates that the pattern is inferred. Abbreviations: *FD*, *FLOWERING LOCUS D*; *SOC 1*, *SUPPRESSOR OF OVEREXPRESSION OF CONSTANS 1*; *LFY*, *LEAFY*; *AP1*, *APETALA 1*; *TFL1*, *TERMINAL FLOWER 1*.

suggesting that FT is required in leaf tissue for this expression to occur (1, 95). Similarly, *CaMV 35S* promoter-driven overexpression of *FT* causes ectopic expression of *API*, *FUL*, and *SEP3* in leaves, which is strongly reduced if the transgene is expressed in an *fd* mutant background (88). These observations are consistent with the idea that the FT/FD heterodimer regulates *API*, *FUL*, and *SEP3* expression in the meristem, and that overexpression of *FT* or *FD* in the leaves causes ectopic expression of the downstream genes.

FT/FD probably activates *API* by directly binding to its promoter, presumably via the DNA binding domain of FD. A C-box, a *cis* element bound by bZIP factors, is present in a functionally important region of the *API* promoter in close proximity to LFY binding sites (95). The role of FT in the heterodimer is currently unclear, but it might provide a coactivator function to the FT/FD complex, and this is supported by a chromatin immunoprecipitation experiment that detected FT associated with the *API* promoter (95). Alternatively, FT might be necessary for posttranslational modification of FD, thereby activating it or targeting it to the nucleus. A putative calcium-dependent protein kinase target site in FD appears to be required for the interaction with FT in yeast two-hybrid assays, supporting the idea that posttranslational modification regulates the interaction (1).

Robust *API* expression is detectable at the SAM four days after a shift from SD to LD in Landsberg *erecta*, at a time when the first stage 1 floral bud is visible (**Figure 4**). By this stage production of the FT signal in the leaves is not required any longer, and the meristem is fully committed to flower independently of *FT* expression in the leaves (18). Therefore, the first molecular event controlled by FT at the SAM upon floral induction is unlikely to be the activation of *API*. In contrast, induction of *SOC1* expression in the SAM is detected much earlier than *API* expression, approximately 16 h after a shift from SD to LD and prior to macroscopic changes at the meristem (12, 80) (**Figure 4**). Induction of *SOC1* is strongly

delayed in either *ft* or *fd* mutant plants, so that FT and FD are required for the earliest marker of floral induction in the meristem that is currently available (80), consistent with gene activation by FT/FD as the earliest step in the floral transition that occurs at the meristem.

SOC1 acts as a floral integrator and is activated by FT-dependent and FT-independent pathways (50, 65, 77, 100). Mutations in *SOC1* cause late flowering under LDs or SDs (12). So far, there has not been a report on the identification of direct *SOC1* target genes, so the order of events after *SOC1* activation is unclear. However, the inverse correlation of *SOC1* and *API* expression (**Figure 4**) may be indicative of a complex feedback loop relationship between different FT/FD target genes (54).

FT-RELATED GENES IN ARABIDOPSIS

A small family of six *FT*-like genes exists in *Arabidopsis*, and these genes might have related functions in floral induction. The proteins encoded by these genes contain a phosphatidylethanolamine binding domain (PEPB) (16). The physiological function of PEPB proteins is widely studied in animals in which they are proposed to act in signaling cascades via protein-protein interactions (16). In *Arabidopsis* the PEPB family comprises, in addition to FT and TSF, BFT (BROTHER OF FT), ATC (ARABIDOPSIS THALIANA RELATIVE OF CENTRORADIALIS), MFT (MOTHER OF FT AND TFL1), and TFL1 (TERMINAL FLOWER 1) (13, 61, 97, 101).

Of these proteins TSF is the most similar to FT, such that the proteins are 81.3% identical. *FT* and *TSF* show similar, but not overlapping, expression patterns in the phloem and significant homology is detected in the proximal parts of their promoters. However, in contrast to *FT*, *TSF* is also expressed at low levels in the basal part of the apical meristem. Expression analyses confirmed that, similar to

FT, *TSF* responds rapidly to varying levels of CO and is repressed by *FLC* and *EARLY BOLTING IN SHORT DAYS (EBS)* (97). In contrast to *FT*, *TSF* expression is not increased in *tfl2/lhp1* mutants, although chromatin immunoprecipitation on chip data suggest *TFL2/LHP1* is associated with the *TSF* locus (90). At least in young plants, *TSF* is expressed at a low level, possibly because of the presence of large retrotransposon and repetitive sequence insertions at the 3' end of the gene. The *tsf* mutation has only a minor effect on flowering time under LDs in the presence of an active *FT* gene, but *ft tsf* double mutants show an additive phenotype, indicating genetic redundancy between the genes (97). The spatial requirement for *FT* and *TSF* mRNA was analyzed using an artificial microRNA directed against both genes (59). Transgenic plants expressing the *amiR-FT/TSF* in the phloem phenocopied the *ft tsf* double mutant, but flowering time was not affected when *amiR-FT/TSF* was expressed in the *FD* domain. This experiment indicates that *TSF* mRNA, like *FT* mRNA, is active in the companion cells of the phloem and is not required in the meristem. Taken together these data indicate that *TSF* could regulate flowering by a mechanism similar to that proposed for *FT*, but so far it has not been reported whether *TSF* protein can move to the SAM along with *FT* (**Figure 3**).

TFL1 has an antagonistic effect on *FT* in the regulation of flowering. Loss-of-function *tfl1* mutant plants flower early independently of day length and form a terminal flower, similar to *FT*-overexpressing plants (13, 40, 44). Conversely, *35S::TFL1* plants flower late in LDs and have a prolonged inflorescence phase in which cauline leaves rather than flowers are produced, a phenotype related to that of *ft* mutants (71). Paradoxically, the *TFL1* transcript is upregulated in the inflorescence meristem through activation of *CO* (82). A current hypothesis is that *TFL1* acts as a competitor of *FT* in the apex to prevent *FT* from converting the SAM into a floral meristem (2). Consistent with this hypothesis, whereas *TFL1* mRNA is

restricted to the center of the SAM, the *TFL1* protein moves beyond its mRNA expression domain and spreads into the entire meristem (17) (**Figure 4**). Although a mechanism of reciprocal competitive binding of *FT* and *TFL1* to *FD* has been proposed as the mechanism underlying this function, at present it is not clear whether the *TFL1* and *FD* proteins can physically interact, because two reports have shown contradictory yeast two-hybrid results (1, 95). A reciprocal single amino acid exchange of *FT* and *TFL1* is sufficient to reverse the function of these proteins (29). The homologs most similar to *TFL1* are *BFT* and *ATC*, but their roles in plant development are unclear. No mutant alleles of *BFT* have been described so far, and *atc* mutants do not show any obvious alteration in flowering time or flower development (61).

The third class of *FT*-like protein is represented by *MFT* (101). *MFT* is equally related to *FT* and *TFL1* and, at the critical position proposed to distinguish *FT* and *TFL1*, *MFT* has an amino acid different from both. *MFT* does not belong to the *FT/TSF* category; nevertheless, overexpression of *MFT* can also cause slightly early flowering in LDs (101), although mutations in *MFT* do not have a perceptible effect on flowering. Nevertheless, to fully understand how these genes contribute to the systemic signaling and meristem functions currently ascribed to *FT*, it will be important to describe the patterns of expression of each gene, to systematically combine null alleles of the different family members, and to determine how these combinations alter flowering time.

FLOWERING OF *ARABIDOPSIS* UNDER SHORT DAYS

Arabidopsis is a facultative long-day plant and therefore eventually flowers under SDs. Under LDs *ft* mutants are late flowering, but reports on the effects of *FT/TSF* under SDs differ. For example, whereas Michaels and colleagues (60) found no effect of *ft* or *tsf* mutations under SDs, Yamaguchi and coworkers

TERMINAL FLOWER 2/LIKE-HETERO-CHROMATIN PROTEIN 1 (TFL2/LHP1): a repressor of genes that are regulated by the Polycomb pathway in *Arabidopsis*

(97) found an effect of *tsf* and a strong enhancement in the *ft tsf* double mutant (60, 97). Nevertheless, even in the absence of both FT and TSF, flowering does occur under SDs, indicating that absence of the systemic signal represented by FT/TSF can eventually be overcome under SDs.

An attractive possibility is that an alternative pathway promotes flowering in the absence of *FT/TSF* and under SDs. Genetic data suggest a major role for GA in controlling flowering of *Arabidopsis* under SDs (96). The *ga1-3* mutation, which strongly impairs GA biosynthesis, prevents flowering under SDs and strongly enhances the *co2* mutation under LDs, so that the *co2 ga1-3* double mutant never flowers under these conditions (72). GA may therefore compensate for the reduced effect of the FT system on SD-grown plants and *co* mutants, and GA does accumulate at the meristem of *Arabidopsis* during the transition to flowering under SDs (21). In *Lolium* GA was proposed to represent a systemic signal that induces flowering at the apex, and GA could represent a second signal in *Arabidopsis* that acts in parallel to the FT system and is not as strongly regulated by photoperiod (42).

CONSERVATION OF THE CO/FT MODULE AND ITS REGULATION IN OTHER SPECIES

Homologs of the *CO* and *FT* genes have been isolated from many monocotyledonous and dicotyledonous species (26, 33, 41, 45, 55, 58, 69, 73, 81, 91, 98). In particular, the function of FT as a promoter of flowering appears to be remarkably conserved in all species tested in detail. Overexpression of *FT* homologs causes extreme early flowering in the dicotyledonous plants poplar (10, 33), tomato, tobacco (51), and *Pharbitis nil* (31) as well as in the monocotyledonous plant rice (45). If *FT* directly encodes the floral stimulus, as discussed above, then this would be consistent with the physiological data suggesting that at least in some cases different plant species produce

the same systemic signal. Furthermore, *FT* mRNA abundance is increased in response to exposure to photoperiods that induce flowering in barley and rice as well as *Arabidopsis* (30, 85, 91, 99). However, in the day-neutral plant tomato, expression of the *FT* ortholog *SFT* is not regulated by photoperiod, although overexpression of *SFT* promotes early flowering and *sft* mutations delay flowering (52). These observations indicate that regulation of *FT* expression by photoperiod through the activity of CO homologous proteins is likely to be highly conserved in plants as distantly related as *Arabidopsis* and rice, but that this connection can be severed in photoperiod-insensitive plants such as tomato.

Activation of *CO* under LDs can be explained by an external coincidence model, as described above. However, in the short-day plant rice, the regulation of the *FT* ortholog is reversed so that its transcription is activated under SDs and repressed under LDs (45). Elegant genetic experiments based on natural genetic variation for photoperiod response in rice, isolation of induced mutations, and construction of transgenic plants demonstrated that the core photoperiod pathway is conserved and promotes flowering under SDs. In rice the *HEADING DATE 1* (*Hd1*) locus encodes the *CO* ortholog (98) and *Hd3a* encodes an *FT* homolog (45). *Hd3a* plays a role similar to that of *FT* in *Arabidopsis*, so that *Hd3a* mRNA levels are higher under SDs than under LDs, *Hd3a* loss-of-function alleles delay flowering under SDs, and overexpression of *Hd3a* causes early flowering (45). However, the role of *Hd1* in rice is more complex than the role of *CO* in *Arabidopsis*, because *Hd1* both promotes flowering and *Hd3a* expression under inductive SDs and delays flowering and represses *Hd3a* expression under noninductive LDs, whereas in *Arabidopsis* *CO* only promotes flowering under inductive LDs (98) (Figure 5). How does *Hd1* have opposite effects on *Hd3a* expression under LDs and SDs? The repression of *Hd3a* expression under LDs could be explained by an external coincidence model similar to that proposed

for *Arabidopsis*. According to this model, under LDs *Hd1* expression coincides with exposure of plants to light, leading to the modification of Hd1 protein and to the repression of *Hd3a* expression. In contrast under SDs, *Hd1* mRNA accumulates only during the night, and in a dark-synthesized form, the Hd1 protein would activate *Hd3a* transcription and thereby induce flowering. Although these results provide a convincing model for how flowering of rice responds to short photoperiods, the response of other short-day plants might be controlled by different mechanisms. Recent evidence suggests that flowering of *Pharbitis nil*, a classical short-day model species for physiological experiments, is controlled by a circadian rhythm set by dusk that induces *Pharbitis nil FT* (*PnFT*) expression only if the night is sufficiently long (31) (Figure 5). The role of PnCO in activation of *PnFT* remains unclear. These experiments suggest that *Pharbitis* measures day length by a different mechanism than that of rice.

Analysis of the *CO/FT* system in poplar provided evidence for the importance of these genes in adaptation to growth at different latitudes. In poplar, the *FT* ortholog *PnFT1* has important functions in bud dormancy as well as flowering (10, 33). In poplar, growth terminates in autumn and bud dormancy is initiated. This is a photoperiodic response induced by exposure to SDs during autumn, and in wild-type plants *PnFT1* expression is reduced on exposure to SDs. Transgenic poplar plants overexpressing *PnFT1* do not terminate growth on exposure to SDs, whereas those with reduced *PnFT1* expression are more sensitive to SDs. Böhlenius and colleagues (21) then tested whether the day length recognized as an SD in the regulation of *PnFT1* expression differed between poplar accessions, and whether this was related to the timing of *PnCO* expression. They studied four accessions collected from locations extending from Germany at 51°N to northern Sweden at 63°N. In day lengths of 17, 19, and 21 h they observed that *PnCO* is expressed at an earlier phase in the southern accessions.

Arabidopsis

Rice

Pharbitis

Figure 5

Regulation of *FT* mRNA expression by day length in different species. In *Arabidopsis* the expression of *CO* at the end of a LD and the light-induced stabilization of the CO protein cause activation of *FT* transcription. Under SD the CO protein does not accumulate, *FT* transcription is not activated, and flowering is delayed. In rice the photoperiodic response is reversed so that the CO ortholog *HEADING DATE 1* (*Hd1*) activates *HEADING DATE 3a* (*Hd3a*) transcription under SD but represses it under LD. The effect of Hd1 on *Hd3a* activation is proposed to be due to light-induced modification of Hd1. According to this model, when rice plants are exposed to light the Hd1 protein is synthesized in a form that represses *Hd3a* transcription, whereas in a dark-synthesized form the same protein acts as a promoter of *Hd3a* expression. In *Pharbitis* *PnFT* transcription is induced under SD, when the rhythm in the activity of a clock-controlled gene (CCG) reaches its peak of expression during the long night. In contrast, during LDs *PnFT* does not accumulate because expression of the CCG is suppressed by light at dawn and never reaches a critical threshold sufficient for *PnFT* induction. White areas denote light, blue areas denote darkness. The blue arrows represent transcriptional activation of the gene named in the arrow. The red hexagons represent transcriptional repression of *Hd3a*. *FT*, *FLOWERING LOCUS T*; *CO*, *CONSTANS*; SD, short day; LD, long day.

Under 19-h day lengths, *PnCO* mRNA expression coincides with exposure of plants to light for the two most-southern accessions but not for the two northern accessions and *PnFT* is expressed under these conditions for the southern accessions but not the northern

accessions. Northern accessions recognize longer day lengths as SDs and therefore induce bud dormancy earlier in the autumn in anticipation of the earlier onset of winter conditions, and this response appears to be adapted to the latitude in which poplar accessions grow through modification of the timing of *PnCO* expression and the consequent expression of *PnFT*.

PERSPECTIVES

Tremendous progress has been made in recent years in understanding the basis of florigen and the control of its expression by photoperiod (see above). However, major questions remain to be solved both in understanding the mechanistic basis of the system in the *Arabidopsis* model and in determining how variation in the system confers the diversity in flowering behaviors observed in nature. Understanding long-distance signaling by FT crucially requires determining whether FT protein is sufficient for this process and acts alone or whether it requires other molecules that are transported along with FT. Similarly, little is known of the mechanisms by which the protein is transported through the phloem and loaded into the meristem. We do not know in which cells FT first acts to promote the earliest steps in floral induction nor the nature of the first signaling steps that are initiated by the arrival of FT protein.

Although the core photoperiod pathway appears to be widely conserved, the broader context in which the photoperiodic response functions is likely to differ significantly in other angiosperm systems. For example, the intersection between photoperiod response and pathways controlling other environmental responses appears not to be conserved. In *Arabidopsis* the vernalization and photoperiod

responses appear to be independent and converge on the regulation of transcription of *FT* and other floral integrators. However, transcription of the wheat *VERNALIZATION 2* gene, which encodes a repressor of flowering that plays a central role in the vernalization response, is reduced either by exposure to vernalization or by exposure to noninductive SDs (19). Such observations suggest that in other species environmental responses that influence flowering time are likely to intersect with the photoperiod pathway and regulate *FT* transcription in ways that could not be predicted from the analysis of *Arabidopsis*.

Finally, time of flowering of widely used summer annual accessions of *Arabidopsis* such as Landsberg *erecta* and Columbia seems to be determined largely by whether *FT* is expressed. Within 1 day of inducing *FT* expression in the leaves the mRNAs of genes associated with flowering are detected at the meristem, and within three days Landsberg *erecta* plants are stably committed to flower. Such observations indicate that regulatory steps in the meristem do not play a large part in determining the flowering time of these accessions, but rather that the meristem response is determined by the timing of *FT* expression in the leaves. However, this cannot be the case in all plants. For example, in perennials different meristems on the same plant respond differently to floral induction, so that some remain vegetative, whereas others are induced to form flowers. Such polycarpic behavior suggests either the existence of mechanisms in the meristem to regulate responsiveness or that leaf-derived signals such as FT are transported differently to particular meristems. The nature of such processes will be elucidated by future experiments and will add to the surprises this beautiful system has given us during the past 70 years.
